and Quinlan, 1977). The propositions as well as the empirical results clearly have stimulated a growing interest in this field. One has to point, however, to a limitation of this literature. Most of this research which is cross-national in design has put only political variables at the center of the analysis. An approach is needed which simultaneously takes into account social, economic and political determinants of personal income inequality.

The basic argument is that the distribution of economic rewards (measured by the size distribution of personal income) is largely a function of the distribution of power. This starting point is the same as that of Lenski (1966). More specifically, Bornschier (1978) suggests that one distinguish three analytical dimensions of power distribution: (1) the aggregate organizational power distribution, (2) the distribution of power in markets, and (3) the power distribution of "steering" located in the political and cultural system.

These dimensions cannot be attached exclusively to specific social actors. Concrete social actors (such as governments, trade unions, multinational corporations

We would like to acknowledge the financial support of the Deutsche Gesellschaft fuer Friedens-und Konfliktforschung (DGFK), Bonn-Bad Godesberg, F. R. of Germany. This funding (AZ. 13-02 Bo 2/1-75) relates to the research project, "Multinational Corporations, Economic Policies and National Development," directed by Volker Bornschier and Peter Heintz at the Sociological Institute of the University of Zurich.

We would also like to thank Christopher Chase-Dunn, Christopher Hewitt, Peter Meyer-Fehr, Richard Robinson, Philippe Schmitter and an anonymous reviewer for their helpful comments on drafts. We alone are responsible for those errors and omissions which remain.

The paper was read at the general conference of the European Association of Development Research Institutes (E.A.D.I.), Milan, 1978.

and so on) are affected and affect all three dimensions of power distribution. Furthermore, in extension of Lenski (1966), politically organized and territorially limited societies (countries) are part of the world capitalist society. Within the power structure of world society, countries occupy, of course, very different structural positions (Heintz, 1969; 1974; Galtung, 1971; Chase-Dunn, 1975; Robinson, 1976; Bornschier, 1976; 1978; and several others).

Research is needed, therefore, to relate dimensions of the power structure of world society to dimensions of internal power distribution in order to explain personal income distribution within countries. We are concerned with the *world economy* based on the spatial division of labor as an important power system of the world. *Multinational corporations* (MNCs) are today the dominant actors within that world economy. This obtains not only for production, but also for the distribution of goods and services since an important and growing part of international trade is channelled by MNCs, thus by-passing the market completely. It is important to keep in mind, therefore, that the institution of the multinational corporation covers various dimensions of economic dependency in the world economy, namely, with regard to capital, technology, organization, international financial flows and foreign trade. Consequently, measures of capital penetration by MNCs have been found to be related to technological dependence as well as to various measures of foreign trade dependence (Meyer-Fehr, 1978; 1979).

A particularly strategic aspect relating individual countries to the structure of the world economy is whether a country takes part in the steering of that economy by being an important headquarter country for MNCs (only about a dozen countries belong to this category), or whether a country is merely penetrated by MNCs and therefore asymmetrically subjected to the forces of the world economy. This is the case with varying degrees of penetration for nine out of ten countries in the contemporary world.

We propose, then, as a basic hypothesis, that the institution of the multina-

tional corporation is an important factor for the distribution of income between and *within* countries. This impact is due to uneven development both between and within economic sectors in the course of MNC-penetration and due to changes in the power structure of the penetrated country which result from the intra-organizational division of labor within MNCs. The tasks and functions of decision making are located mainly in the headquarter country, whereas more standardized and routinized tasks are located in the penetrated countries (for more details, see Bornschier, 1976). There exists, of course, income concentration prior to MNC-penetration. The process of superimposed stratification (*Ueberschichtung*) which is the present day result of the spread of MNCs often is rooted historically in colonial subordination. Previously existing inequalities between and within countries are dynamically reproduced in the course of the performance of the system of MNCs. A point in case is the operation of industrial MNCs in the domestic markets of poor countries. This depends on a sufficient prior concentration of income in order to make these markets attractive, i.e., the existence of sufficient *effective* demand for MNC products which are highly standardized worldwide.

Our hypothesis is that MNCs—besides often relying on previous income concentration—contribute, *ceteris paribus*, to further increasing income inequality by affecting the power distribution. Here clearly arises a problem of causal inference since we have no time series for income inequality. With the help of path analysis we nevertheless try to make preliminary causal analyses by testing whether: level of MNC-penetration → degree of inequality in personal income distribution. This test design should not, of course, be interpreted as excluding causal connections running in the direction opposite to that sketched above. Furthermore, we want to remind the reader that our path analysis is based on covariations and is therefore only suggestive. The question whether MNC-penetration *increases*, *ceteris paribus*, income inequality thus requires further tests with time series.

The Two Topics of the Empirical Analysis

Cross-national analyses concerning the empirical relationship between MNC-penetration (or foreign capital penetration in general) and income inequality so far presented in the literature (Chase-Dunn, 1975; Bornschier, 1975; 1978; Robinson, 1976; Bornschier and Ballmer, 1978; Bornschier et al., 1978) do not take into account the *two* different dimensions of being related to the world economy through MNCs. Namely, they do not take into account whether the unit is penetrated by MNCs (subsequently denoted as PEN), or whether it is a headquarter country (denoted as HQS). Therefore, evidence is compiled on the degree to which these measures have inverse and/or symmetrical effects.

Secondly, previously cited evidence concerning the relation between MNC-penetration and income inequality leaves open the empirical issue of the specific mechanisms by which the relation comes into being. In the theoretical framework of Bornschier (1978), a number of hypotheses has been developed based on three analytical dimensions of power distribution. Several of these hypotheses will be tested. The logic of the model can be graphically represented as follows: MNC-penetration → power distribution → income inequality. Our method of empirical demonstration is that the statistically measured direct effect of MNC-penetration on personal income inequality is reduced to null once intervening variables are introduced into the regression equation.

EFFECTS OF MNC-PENETRATION AND HEADQUARTER STATUS

We look at the results in Table 1 to seek an answer to the first empirical question, i.e., whether MNC-penetration and headquarter status have inverse and/or symmetrical effects. For this purpose a sample of 50 countries has been used. The sample size is determined by the availability of data on the various intervening variables which are of main interest.¹

¹ In the sample of 50 countries various data for *intervening* variables have been estimated (see notes and Appendixes). This has been done to keep

The five indicators for our dependent variable, i.e., personal income inequality, are: the Gini index, which provides an indication of the degree of overall income inequality (Gini); the share of the upper income class in total income, i.e., the share of the top 5% of income receivers (T5); the share of the upper-middle income class, i.e., the fifth quintile (Q5); the share of the middle income class, i.e., the fourth quintile (Q4); and the share of the lower income class in total income, i.e., the combined first, second and third quintile (Q1-3).²

The time of the income surveys varies for the countries. The median year is 1968. As far as possible, the time-period for the measurement of the predictor variables has been matched exactly to the time-period for the measurement of income inequality (see notes).

In Table 1 the results of multiple regression analysis are presented. The regressions relate the degree of MNC-penetration (PEN, measured as the total stock of foreign direct investment in relation to total energy consumption and population)³ and the level of headquarter

the sample constant across the various analyses without losing too much information by listwise deletion. The crucial relationships for a test of our hypotheses, however, are also checked by bivariate correlations with pair-wise deletion of estimated data. The results are reported in the correlation matrix in the Appendixes. They show that the relations are rather similar (in some cases even stronger) if one excludes the estimates. Note that the sample of 50 countries does not include five centrally planned socialist countries for which no sufficient data on intervening variables are available (this does not apply to Yugoslavia, a socialist market economy). All the data employed in the analyses will be included in a data compendium (Ballmer and Scheidegger, n.d.).

² The data have been described in Bornschier (1978). Income refers to income before taxes and is from all sources. The income unit is the household; there are, however, several exceptions, i.e., the tax-paying unit, the income receiver or the individual. The main source for the data is the World Bank compilation of data on personal income distribution (Jain, 1975). This was supplemented by various other sources.

³ The concept for the operationalization is to relate the total stock of foreign direct investment (KFDI) to the total stock of capital (K) of the penetrated country. This ratio has to be corrected for the large differences in capital intensity across countries at different levels of economic development. This has been done by multiplying the ratio with the ratio of

⁵ The data for the logged income per capita ($\log Y_n$) relate to 1965 and are in constant market prices and U.S. \$ of 1964. The source is I.B.R.D. (World Bank), 1971. The level of average surplus is understood in terms of Lenski's (1966) usage.

proved by a high headquarter status; whereas MNC-penetration does increase income inequality.

Furthermore, a function of the level of income per capita is significantly related to income inequality. It is a curvilinear relation. At a low level of surplus, income inequality on the average is lower than at a medium level of surplus; whereas at the high levels of surplus, income inequality is again comparatively low. For a further theoretical and empirical analysis of this curvilinearity see Bornschieer (1978) and Ahluwalia (1976).

The absence of a significant negative relationship between headquarter status and income inequality is only a first result of a preliminary test of the complementary hypothesis suggesting symmetrical effects. The relationship between MNC-penetration and income inequality substantiates the previous findings cited above. It should be noted that the correlation in the largest possible sample of 72 countries (Bornschieer, 1978:34) is considerably stronger (PEN/Gini: $r=.47$) than in the present sample of 50 countries (PEN/Gini: $r=.30$).⁶

We have measured MNC-penetration by foreign capital dependency because within our theoretical perspective we also are interested in organizational aspects stemming from the direct involvement of foreign actors within dependent countries. The effect of PEN as shown in Table 1 remains also significant if foreign trade dependency is controlled for.⁷ We like to

point out, however, that both aspects of dependency are linked theoretically by the fact of the institution of the multinational corporation within the world economy as mentioned before.

EFFECTS OF MNC-PENETRATION ON PERSONAL INCOME INEQUALITY

In this section empirical explanations of the effects of MNC-penetration on personal income inequality are explored. We follow the research design outlined above by looking at the following theoretically relevant intervening variables: (1) the organizational power distribution, (2) the power distribution on the labor market, (3) the extent and the nature of the "steering power" (Steuerungsmacht) of the state.

(1): Organizational Power Distribution

We examine for the effect of the following parameters of the global organizational power distribution at the level of each national unit: (1) the extent of hierarchization of control; (2) the shape of the distribution of the labor force across the various hierarchical levels; and (3) the extent

1965 according to the procedure proposed by Gal-tung (1971: 102; trade composition index). Note that VERT is scaled in such a way that high values indicate a favorable position with regard to vertical trade. PEN 1967 and VERT 1965 are correlated ($r = -.43$, $N = 49$). Regressions of Gini on:

	HQS	PEN
N=49	-.05 (0.32)	.23 ^a (1.77)
N=35, LDCs only	-.05 (0.30)	.37** (2.06)
VERT 1965	f(Yn)	R ²
-.27*	.35**	.36**
(1.82)	(2.19)	(2.80)
-.38**	.07	.37**
(2.10)	(0.46)	(2.45)

This result shows that our indicator of MNC-penetration, representing also aspects of foreign trade dependency, is not statistically reduced to insignificance in its effects on income inequality by controlling foreign trade dependency as measured by VERT. Since we are interested in a more comprehensive analysis of the MNC-impact we do not control in the following for foreign trade dependency, which we see partly as one aspect of MNC-penetration.

⁶ The relationship is considerably stronger for underdeveloped countries within the 50 cases, i.e., PEN/Gini: $r = .50$ for 35 cases. This may be attributed: (1) to the fact that for various highly developed countries the effect might be compensated for by a high MNC-headquarter status; (2) to the organizational process of superimposed stratification which is assumed to be more pronounced in underdeveloped countries; and (3) to the possibility that a high and increasing income inequality is a prerequisite as well as a sociopolitical consequence especially in underdeveloped countries (see also below: steering power of the state). In addition, one may point to the finding of Chase-Dunn (1975) that foreign capital penetration goes together with high sectoral income inequality which seems to not apply to developed countries (Bornschieer, n.d.).

⁷ The foreign trade dependency measure we control for is the index of verticle trade (VERT, measuring the trade composition with regard to manufactured goods and raw materials). It is computed for

to which power is shared with expertise.⁸ Theoretical analyses of these parameters, as well as propositions concerning their complex interplay in the course of organizational evolution, have been presented elsewhere (Bornschieer, 1977; 1978).

Here, the hypothesis that the institution of the multinational corporation affects the evolution of the organizational power distribution is examined. It is based on the following theoretical suppositions. Power sharing with expertise takes place mainly in the organizational context of the company headquarter staff. The subsidiaries of MNCs operating in the penetrated country are dependent and incomplete organizations with special "line" functions in the MNCs' internal division of labor. In general, standardized and routinized functions prevail in such subsidiary operations. This pattern affects the internal structure of dependent organizations and thus the distribution of the labor force, as well as the degree of inclusion of expertise. At the same time, however, the transplantation of large-scale subsidiaries contributes to the hierarchization of control and increases the heterogeneity in the total system of organizations with respect to size, capital intensity and regional distribution of plants within the penetrated country. The specific hypotheses are that the higher the MNC-penetration, the higher the hierarchization of control and the higher the heterogeneity within the total organizational system and, hence, the less the trend towards bureaucratization and the lower the power sharing with expertise. The overall consequence is a disparity in the development of structural parameters of the aggregate organizational structure.

The latter two parameters have been operationalized. It is proposed that power sharing with expertise (PSE, measured as

the number of experts per hundred executives and owners outside agriculture)⁹ as well as the trend towards bureaucratization (BUR, measured as the number of clerical workers as percent of the labor force outside agriculture)¹⁰ increases the share of the middle and lower income class (bottom four quintiles) at the expense of the income share of the upper income class. Through this process the whole income inequality (Gini) is reduced.

The two organizational power variables measuring the power sharing with expertise and the bureaucratization (PSE, BUR) are positively related ($r=.56$). Both show a very strong correlation with the logged level of income per capita, $\log Y_n$ ($r=.73$ and $r=.76$). These correlations support the theoretical view (see Bornschieer, 1977) that the parameters of the aggregate organizational power structure are closely related to labor productivity which corresponds to income per capita. This theoretically expected high correlation poses, however, severe problems of multicollinearity in regression analysis. Highly interrelated independent variables mean that the relative impor-

⁹ The data for the operationalization of PSE (power sharing with expertise) is taken from the Yearbook of Labour Statistics (ILO, various years). PSE is equal to the square root of salaried professional, technical and related workers/employers and workers on own account outside agriculture + salaried administrative and managerial workers). The square root is used to correct the fact that experts, as their relative number increases, are increasingly hierarchically organized. The indicator has been time matched. In several cases, however, this has not been completely possible. In addition, for four countries only data on *total* professional workers are available; in these cases adjustments have been made to estimate the salaried only (the method was to take four-fifths of the total). For one country very early information has been extrapolated and the data for one country is estimated on the basis of information for other countries in the region with similar labor productivity (see Appendixes).

¹⁰ The aim of the operationalization is to measure the relative importance of clerical workers (without managers and experts). The source is the same as for power sharing with expertise. BUR is equal to the ratio of the clerical and related workers (without sales personnel) to the total labor force outside agriculture. This is again time matched, though not completely due to lack of suitable data for some countries. Data for the same two countries as in the case of PSE have been estimated using the same procedure.

⁸ Power sharing with expertise as a theoretical concept does not necessarily imply on the level of concrete roles that power is shared in a strict legal sense. Experts often are coopted into power (into an important but nevertheless subordinate position). But also in this frequent case it is implied that power holders have to pass over some benefits from power. For example, capital as a basis of power (right to command) can be cumulated to a great extent, but knowledge is, in general, necessarily more dispersed among a wider group (cf. Bornschieer, 1978).

tance indicated by the partial regression estimate is unreliable. Therefore, we have to exclude either the level of average surplus ($\log Y_n$) or both measures of organizational power distribution (PSE and BUR) from the regression.

Since we think that the relation between the level of economic development and income inequality is theoretically less promising than the relations with organizational power variables which have a more specific content, we exclude $\log Y_n$ from the regression.¹¹ There is, in addition, also a technical argument for the preference for PSE and BUR. If the correlation between independent variables is high as compared with their correlation with the dependent variable, the partial regression estimates may be poorer indicators of their relative importance than the zero-order correlation coefficient. Since both measures of organizational power distribution are more highly correlated with income inequality than $\log Y_n$ (see Appendixes) the preference for PSE and BUR is, therefore, also justified on statistical grounds.

The two organizational power distribution variables pertain to the nonagricultural segment of the society. Therefore we have to introduce an indicator of a basic structural feature of the *agricultural system* which is of great relative importance for a majority of countries. We use the concept of the degree of concentration of traditional economic power (TEP)¹² and

operationalize it in terms of the concentration of ownership of arable land. Such concentrated traditional economic power can be assumed to be fused often with export oriented interests linked to the world market (Kaztman, 1972; Heintz, 1969). This form of ties of traditional local elites with the world economy seems to be conducive to MNC-penetration. The correlation between land concentration and MNC-penetration (TEP/PEN: $r = .46$)¹³ suggests this.

The regression results in Table 2 show clearly significant relations between the indicators of organizational power distribution (BUR, PSE) and measures of income inequality which move in the hypothesized direction. The greater the trend towards bureaucratization, the lower is overall income inequality and the less unequal are the shares of income classes. However, power sharing with expertise, on the one hand, reduces significantly only the share of the top income class (T5) and, on the other hand, increases significantly the share of the middle class in total income (Q4). The share of the lower class as well as total inequality are not affected by this change in the power distribution.

Furthermore, the measure indicating the concentration of traditional economic power (TEP) also is related to income inequality. This is significant for three out of five measures of income inequality. Finally, Table 2 reveals a very important finding within the logic of our research design. Once variables of the organizational power distribution and of the traditional economic power are introduced along with MNC-penetration into the regression of personal income inequality, the *direct* effect of MNC-penetration is substantially reduced (in the case of

¹¹ If one neglects the problem of multicollinearity and introduces a function of logged income per capita into the regressions of Table 2, the direction and the pattern of associations of BUR and PSE with income inequality hold (see also Bornschie, 1978, for 54 cases). The magnitude and significance of the partial regression estimates for our 50 cases are reduced however. Also, the significance of the total regression is lower.

¹² The indicator is based on the Gini index of land distribution given by Taylor and Hudson (1972) (we used, in addition, the first edition of this handbook). The data relate mainly to ca. 1960. Since data for several countries have been estimated by using qualitative information, the interval scale has been reduced to an ordinal scale (Gini below .445:1, from .446 - .520:2, from .521 - .595:3, . . ., from .896 - .970:8). This simplified scale makes possible a relatively unproblematic assignment of scores to countries with no information in the basic source (namely, in the case of 11 countries out of 50). The assignment

of ranks is based on qualitative information mainly taken from Nohlen and Nüscheler (1976).

¹³ This does not apply, however, to foreign investment in agriculture itself (TEP/PEN in agriculture: $r = -.03$, $N = 35$ LDCs). Correlation results thus suggest that strong landed elites seem to prevent foreign investment in agriculture, but favor it in extraction (TEP/PEN in extraction: $r = .32$, $N = 35$ LDCs) and especially in manufacturing (TEP/PEN in manufacturing: $r = .46$, $N = 35$ LDCs). Data for penetration in sectors are from Bornschie and Ballmer (1978).

Table 2. Income Inequality Measures Regressed on Organizational Variables (PSE, BUR), Land Concentration (TEP) and MNC-Penetration (PEN) (N=50)

Predictors	Gini	T5	Q5	Q4	Q1-3
PSE	-.11	-.30**	-.16	.35**	.06
(t)	(0.76)	(2.06)	(1.23)	(2.59)	(0.42)
BUR	-.49**	-.35**	-.52**	.38**	.52**
(t)	(3.53)	(2.55)	(4.05)	(2.88)	(3.75)
TEP	.32**	.23*	.32**	-.21*	-.34**
(t)	(2.42)	(1.70)	(2.31)	(1.68)	(2.50)
PEN	.13	.16	.10	-.06	-.10
(t)	(1.04)	(1.32)	(0.86)	(0.54)	(0.83)
R ²	.42**	.42**	.50**	.47**	.41**
(t)	(3.15)	(3.13)	(3.64)	(3.43)	(3.09)

Note: for notes see Table 1.

Gini the beta is now .13 as compared with the clearly significant beta of .34 in Table 1).

We suggest the following causal interpretation of our statistical results: (a) MNC-penetration acts via a stabilization of traditional power on the distribution of income; (b) MNC-penetration retards the evolution of organizational parameters. Since the production thus takes place in the framework of a more unequal organizational power distribution, the income distribution is consequently more unequal. We provide more detailed evidence with the help of path analysis (Figure 1). In the path diagram the organizational variables (PSE and BUR) are taken as endogenous variables. PSE as well as BUR are strongly related to the level of surplus or labor productivity ($\log Y_n$). This is seen as a snap shot in a self-sustained process. An increase in the division of labor increases labor productivity and average surplus. The higher productivity in turn provides the resources (in manpower as well as capital) which make possible a progressive increase in the division of labor, including, of course, an increase in capital intensity.

Between MNC-penetration (PEN) and the organizational power distribution variables (PSE and BUR) clearly significant negative paths can be observed.¹⁴

¹⁴ The path coefficients to the organizational variables have been estimated including the variable TREND. The results are not given for reasons of easy presentation. TREND represents the time-point of measurement. Since both PSE and BUR as well as PEN have been time matched to the measurement of income inequality and since there is a general increase in these variables over time, TREND controls

The static path analysis thus lends some support to the dynamic hypothesis that MNC-penetration acts on income distribution via a retardation in the organizational evolution.

(2): *Power Distribution in the Labor Market*

We hypothesize that the power structure in the labor market is a determinant of income distribution. We consider three concepts as a basic characterization: bargaining power of labor in wage and labor conflicts (BPL), supply pressure on the labor market caused by demographic changes (SPD), supply pressure on the labor market caused by technological changes, net of demographic changes (SPT).

The bargaining power of labor is assumed to be the central feature of the labor market. We assume that it helps to explain differences in income inequality. For such an international comparison one should not rely on the frequency of strikes. Repression, on the one hand, and highly institutionalized wage bargaining on the other, make the frequency of strikes a rather doubtful cross-societal indicator of the bargaining strength of labor. Also the degree of unionization does not seem to be comparable due to the low equivalence of trade union systems. For example, in trade unions dominated by the state where membership is compulsory, the degree of unionization is not a meaningful indicator for the strength of labor.

for the disturbing factors due to the different points in time. The control variable TREND is not related, however, to income inequality.

Figure 1. Path Diagram to Table 2

Finally, the number of persons involved in strikes or the number of working days lost due to strikes are not very significant either, because such measures are heavily influenced by the frequency of wage conflicts, depending on the degree of institutionalization, rationality or suppression. We suggest an indicator of the bargaining power of labor (BPL) which does not imply or, at least, partly overcomes the above mentioned shortcomings. The indicator BPL is operationalized as the total participation of workers per strike, averaged over a five-year period which has been time matched to the measurement of income inequality.¹⁵ In the case of rare strikes, this indicator, nevertheless, grasps the phenomenon of "warning" strikes which are intended to signal labor's strength despite general repression

or despite a high institutionalization of conflict regulation. This indicator also captures the aspect of concerted action on labor's side in wage disputes. Labor organizations which are fractionalized and thus do not act jointly cannot attain a high general level of threatening power as measured by BPL, even if the laborers of some plants or some of the unions go on strike frequently.

We propose that high bargaining power of labor is reflected, *ceteris paribus*, in lower income inequality. MNC-penetration is supposed to weaken the bargaining power of labor. This is due to a complex of socioeconomic and sociopolitical factors. (1) Given their organizational, superimposed stratification (Ueber-schichtung), MNCs favor an increasing fractionalization of labor. Their strategy of relative wage and fringe benefit privileges demonstrated by their paying in general higher wages than the going rate (cf. Bornschie, 1976; 1978, and the references there), strongly contributes to the creation of labor aristocracies which are unfavorable to the concerted action of labor. (2) MNCs, due to their assumed relative power position within the sociopolitical system, can be supposed to exert influence on governments by which the political and/or legal framework of wage conflicts is altered. This can, but does not necessarily go so far as to involve a prohibition of trade unions and/or

¹⁵ The source is the Yearbook of Labour Statistics (various years). BPL has been transformed to an ordinal scale (ranging from 0.5 to 10) to allow a less problematic assignment of scores to those countries where estimates have to be made on the basis of qualitative information (11 out of 50 cases). The main sources for this additional information are: Leminsky and Otto (1975), country reports on the trade union system by the Forschungsinstitut der Friedrich-Ebert-Stiftung (FR of Germany), and, among others, *Le Monde Diplomatique*. In the case of Yugoslavia the lowest possible value on the ordinal scale has been assumed. We tested also an alternative indicator, i.e., workers striking as a proportion of potential strikers. The results are similar, but not so strong.

strikes. However, one also can point to another argument, i.e., that MNCs often might be rather reluctant to invest considerably in those countries where labor's position is strong. This could also act in the direction of a negative covariation between MNC-penetration and labor's strength.

We control for two aspects of the supply pressure on the labor market. The demographic pressure (SPD) is measured as the growth rate of the labor forces between 1960–1975.¹⁶ This growth of the labor force is often likely to affect negatively the bargaining power of labor. Therefore, it should affect income inequality indirectly.

The supply pressure caused by technological change (SPT) is a possible result of capital intensification. This does not necessarily mean that a substitution of labor by machines will result in a factual or visible surplus of labor. This is only the case if capital equipment per working place (capital intensity) grows at a faster rate than the total stock of capital. We propose to measure the indicator SPT in terms of the difference between the growth rate of capital intensity and the growth rate of the capital stock between 1967–1973, net of demographic changes.¹⁷ SPT thus indicates a tendency towards structural underemployment which is not the result of a relative shortage of labor. MNCs utilize, in general, capital intensive production in developed as well as in underdeveloped countries. Given the abundance of labor in most underdeveloped countries, MNCs, thus, contribute to increasing the structural surplus of labor. The hypothesis is that MNC-penetration is associated with an increase in the technological supply pressure on the labor market (SPT). As SPT measures

only a tendency towards structural underemployment, the direct relation with income inequality is not likely to be observable. However, SPT presumably eventually affects the income distribution indirectly by weakening labor's position in wage conflicts. Even if structural upward mobility chances are relatively high (increase in bureaucratization and power sharing with expertise) the technological supply pressure on the labor market is nevertheless likely to affect labor's position. An orientation or illusion of upward mobility may weaken class solidarity. On the other hand, a feedback from the strength of labor is likely. High bargaining power may favor the substitution of labor by machines.

In Table 3 the three variables characterizing the labor market (BPL, SPD, SPT) are introduced, together with MNC-penetration, into the regressions. A function of the logged level of income per capita (average surplus), i.e., $f(Y_n)$, is introduced, in addition, as in Table 1, since there exists no substantial collinearity with the variables of the labor market. The bargaining power of labor, our central variable of the labor market, shows a clearly significant relationship with each of the five income inequality measures in Table 3. The hypothesis thus is supported: The higher the strength of labor, as measured by BPL, the lower the income inequality. We do not want to exclude, however, the opposite causal interpretation which also makes sense. If one takes income inequality as an indication of the power structure, then one could argue on the basis of the result that the likelihood of labor's conflict articulation is higher, the lower the power concentration. This possible two-way causation obviously needs further research with time series analysis.

The other variables of the labor market, those indicating demographical and technological supply pressure (SPD and SPT), do not show any direct relationship with income inequality. The logged level of income per capita again shows a curvilinear relation with income inequality (as in Table 1).

Finally, once variables characterizing the labor market are introduced together

¹⁶ The growth rate is the quotient (1975/1960). The source of the data is the Yearbook of Labour Statistics (ILO), and ILO (1977).

¹⁷ The capital stock for 1967 and 1973 is computed according to Meyer-Fehr (1978) and Borschier (n.d.). Capital intensity is the total capital stock divided by total labor force. Since the difference between the growth rate of capital intensity and capital stock shows a close negative relationship with the demographic pressure variable (SPD), we measure the technological supply pressure (SPT) *net*, i.e., by the residuals from the linear regression on SPD.

Table 3. Income Inequality Measures Regressed on Labor Market Characteristics (BPL, SPT, SPD), MNC-Penetration (PEN), When a Function of the Level of Average Surplus ($f(Y_n)$) Is Controlled for ($N=50$)

Note: for notes see Table 1.

with MNC-penetration into the regressions, the *direct* effect of MNC-penetration is considerably reduced (the beta in the case of Gini as dependent variable is now .21 and not significant any more; as compared with .34 in Table 1 which was clearly significant). This is the same change as in the case of the organizational variables. Therefore, evidence suggests that MNC-penetration affects power distribution in the labor market. We can provide more detailed evidence with the help of path analysis.

The path diagram to Table 3 (Figure 2) shows a significant negative path from MNC-penetration (PEN) to labor's strength (BPL). This is consistent with the hypothesis. One should remark, however, that the empirical evidence based on covariations does not rule out the argument that labor's strength may keep MNC-penetration relatively low. The path from MNC-penetration (PEN) to the ten-

dency for structural underemployment (SPT) is positive as hypothesized and clearly significant. But though the path from SPT (technological supply pressure) to labor's strength (BPL) is negative as expected, it is clearly not significant, beta = -.06 (not included in the diagram). As expected, demographic pressure (SPD) negatively affects labor's position (BPL). The path coefficient just fails to be significant.

(3): Steering Power (*Steuerungsmacht*) of the State

We are concerned here with an empirical evaluation of general prerequisites and basic aspects of the steering power of the state which is a potential source of income redistribution (Cutright, 1967; Jackman, 1974; Robinson, 1976; Robinson and Quinlan, 1977; Hewitt, 1977). We suggest that two dimensions are important: (1) the material scope of the steering power of the state, and (2) the character of state intervention into the economy. For the first aspect we consider government revenues as a percentage of gross domestic income (GVR).¹⁸ For the second aspect we consider two variables:¹⁹ (i) the share of pub-

Path coefficients, in brackets t-ratios. The coefficients without t-ratios are zero-order correlations.

N=50.

Figure 2. Path Diagram to Table 3.

¹⁸ The source of the data is I.B.R.D. (World Bank), 1976. The data for "1967" are the average of 1965 and 1970.

¹⁹ The variable social insurance program experience (Jackman, 1974; Robinson, 1976) has been tested, too. But it was excluded from the reported analyses because of its rather high collinearity with government revenue ($r = .76$).

Table 4. Income Inequality Measures Regressed on State Characteristics (GVR, PIV, GIT) and on MNC-Penetration (PEN) (N=50)

Predictors	Gini	T5	Q5	Q4	Q1-3

Note: for notes see Table 1.

lic investment in total investment (PIV)²⁰, and (ii) the extent of government's general intervention in the economy which includes the incidence of nationalization policy (GIT).²¹ In this section we shall neither consider all aspects of the state's role for income distribution nor shall we consider the determination of the state's action by the character of the distribution of private power (see Robinson and Quinlan, 1977; Bornschier, 1978).

With respect to the steering power of the state, we shall examine first the relationship between the above introduced variables and income inequality. For regression analysis again the problem of multicollinearity arises (see above in the context of organizational power distribution variables). Government revenue (GVR) and logged level of income per capita (log Yn) are highly correlated ($r=.75$). We argue in the same way as in the case of the organizational variables and exclude the function of the logged income from the regression.²²

The regression results in Table 4 show that only one of the new variables, i.e., government revenue (GVR) as a measure of the redistributive *potential* of the state, is clearly related to more income equality. The results for the measures of the involvement of the state in the economy (PIV, GIT) are not significant. Finally, if variables of the state are introduced together with MNC-penetration into the regression, the partial regression coefficients for MNC-penetration are not reduced substantially and remain significant (in the case of Gini the beta of PEN changes little; it is now .33 as compared with .34 in Table 1).

The path analysis relating to Table 4 will not be presented in detail. We would like to mention only that the path from MNC-penetration (PEN) to government revenue (GVR), net of the logged level of income per capita (average surplus), is negative. However, it is of little empirical weight and is insignificant (beta: $-.15$, $t=1.54$). This is consistent with the hypothesis that MNCs are not primarily and unconditionally interested in a low level of government revenue. A case in point is the industrial production in developed as well as underdeveloped countries. This involves considerable costs for infrastructure and for other measures which provide or improve the preconditions for MNC-penetration. Therefore, in general, it is not likely that MNCs try to keep public expenditures low.

If government revenue is an important variable for the redistributive *potential* of the state and if this potential, *on the average*, seems to promote a more equal in-

²⁰ The source is I.B.R.D. (World Bank), 1971. The data refer to 1967 with several minor time deviations reported in the source. A few estimates made by Berweger and Hoby (1978) have been included.

²¹ The indicator GIT is taken from Berweger and Hoby (1978) and refers to 1965. The indicator was constructed by Berweger and Hoby with a content analysis of information provided by Business International.

²² If the problem of collinearity is neglected and a function of logged income per capita is introduced along with GVR into the regressions of Table 4, the direction and pattern of association of GVR with income inequality remain the same. The magnitude and the significance are, however, reduced. Also the significance of the total regression is then lower.

come distribution (also without taking explicitly into account political power distribution), then the question arises whether high MNC-penetration affects the use of the state's financial resources. The hypothesis can be put forward that, driven by self-interest, MNCs try to influence the pattern of purposes as well as the pattern of priorities of state expenditures. Since the concrete policies of the state are dependent on the power constellation of social actors (including the interest of state actors itself), the effective realization of the interests of MNCs depends on changes in the power constellation within both the system of parties as well as administrative action. More precisely, the argument is that MNCs use direct and indirect political pressure (legal as well as illegal, e.g., bribery) to bring about a pattern of purposes and a pattern of priorities of government expenditures which favors them. Indeed, their demand for infrastructure, which is necessary for their type of capital intensive production, cuts down the resources which would be potentially available for a redistribution of income to poorer regions and to poorer segments of the population. But MNCs probably do not only block possible redistributions indirectly by cutting down what is available for such purposes. They also are vitally opposed to any redistributive policy that withdraws money from those who are actually or potentially their customers; in other words, any policy which transfers money to poorer segments of the population. Such poorer segments of the population, under the condition of low average income and high income inequality, still are not able to provide an *effective* demand in the markets dominated by MNCs. From the point of view of MNCs, this money would trickle off and they would lose sales. And apart from this argument within the logic of the market, MNCs are opposed because any extensive redistribution of income is feared as a threat to the stability of the dominant sociopolitical coalition which they support and by which they are also supported.

Therefore, we propose that under a condition of high MNC-penetration government resources are likely not to have an income equalizing effect. Rather, the

purposes as well as the pattern of priorities of public expenditures are likely to increase income inequality. With respect to this hypothesis, however, we propose to introduce a restricting marginal condition, namely, scarcity of resources, i.e., a low level of surplus. In a situation of relative abundance MNCs might not resist a policy of redistribution favoring the poor, because (1) the high level of surplus makes it possible that their specific demands for public expenditures leave enough resources for redistribution, and (2) a redistribution to lower income classes under this condition is not likely to cut down but to increase the effective demand on markets which MNCs dominate (a Keynesian argument, cf. Bornschier and Ballmer, 1978: 39-44).

In order to present some preliminary evidence for the hypothesis we turn to the analysis of covariance in Table 5. Table 5 includes regressions of three measures of income inequality (T5, Q4, Q1-3) on government revenue (GVR), MNC-penetration (PEN) and a dummy variable indicating scarcity of resources (SR-Dummy).²³ With equations 1.2, 2.2 and 3.2 the hypothesis is tested in its unconditioned form. This is done by introducing the interaction term: government revenue under the condition of high MNC-penetration (GVR times PEN-Dummy).²⁴ The interaction terms in this set of equations are not significant. Thus the hypothesis is not supported.

The equations 1.3, 2.3 and 3.3 test the same hypothesis in its conditioned form, i.e., scarcity of resources. The interaction term now takes the values of GVR only if PEN is high *and* if resources are scarce (GVR times PEN-Dummy times SR-Dummy) (see fn. 23). Whereas the basic effect of government revenue (GVR) is related to *less* income inequality, the interaction of government revenue with high MNC-penetration and scarcity of re-

²³ The dummy variable for scarcity of resources (SR-Dummy) takes the value one for all low income countries and the value zero for the other, i.e., U.S., Canada, northern and western Europe (plus Italy), Japan, New Zealand and Australia.

²⁴ PEN-Dummy takes the value one for MNC-penetration values above the mean, otherwise it takes the value zero.

Table 5. Government Revenues Affecting Income Inequality; An Analysis of Covariance (N=50)

Dependent variables; equations	Predictors			GVR times

Note: for notes see Table 1.

sources is related to *more* inequality. This is clearly significant for the share of the upper income class in total income (T5) and significant for the share of the lower class in total income (Q1-3). The results with Gini and Q5 as inequality measures (not included in the table) are very similar to those for T5 and also clearly significant.

These results lend some preliminary support to the conditioned hypothesis that MNCs act in poor countries on income inequality by stabilizing and by contributing to a specific dominant political power constellation. Through this power constellation the state in such countries seems not only to be prevented from adopting a policy of redistribution of income to the poorer segments of the population, but seems also to contribute to higher income inequality. This is the assumed consequence of a policy of expenditures which follows a pattern of items and priorities favorable for the dominant political constellation of which MNCs are part.

SUMMARY MODEL AND DISCUSSION

In the summary model we have put together those variables from the previous analyses which had a clearly significant impact on the comparative income distribution. MNC-penetration itself is not included because the direct effect is very small once the variables measuring power distribution are incorporated. We have reintroduced, of course, MNC-penetration in the final summary path diagram since it is regarded as a primary, antecedent causal agent of the whole process. From the analysis of the state variables, we take government revenue as percent of total income (GVR) as a mea-

sure of the redistributive potential of the state. And from the analysis of the power distribution on the labor market, the bargaining power of labor (BPL) emerged as the most significant. In the case of organizational power distribution, two variables are clearly significant: (1) the distributional change of the labor force towards bureaucratization (BUR) and (2) the power sharing with expertise (PSE). In the case of PSE, however, the collinearity with government revenues is rather high ($r=.73$). Therefore, we do not introduce them both into the same regression. The correlation of BUR with GVR is only $r=.56$. We use, therefore, BUR as a residual factor characterizing organizational power distribution. Finally, we include the concentration of the traditional economic power (TEP).

These four intervening variables, i.e., intervening between MNC-penetration and income inequality, represent important macroaspects of the modern organizational system, the organization of agriculture, the labor market and the state. The results in Table 6 show that each of these four final variables is related to the five measures of income inequality. Out of the 20 coefficients estimated in the regression only three fail to be clearly significant. Of these three measures, two are moderately significant and only one is insignificant.

The trend towards bureaucratization is particularly strongly related to a higher share of the lower income class (bottom three quintiles) to a lower share of the top quintile and to lower overall inequality. Traditional economic power is especially related to a higher share of the top 20%, to a lower share of the lower class and to

Table 6. Summary Regressions of Income Inequality Measures (N=50)

Note: for notes see Table 1.

higher overall inequality. The bargaining power of labor equally affects four measures in the direction of less inequality. Only its association with a higher share of the middle class (fourth quintile) is somewhat lower. The share of government in total income is particularly strongly related to a higher share for the middle class (Q4) and to a lower share for the upper income class (T5). The other measures of income inequality are less affected. This pattern also is reported in Rubinson (1976) and Rubinson and Quinlan (1977).

Despite these differences in the relative beta weights of the predictors for the five measures of personal income inequality, the overall importance of the four final predictors is fairly similar. The average of the beta weights across the five measures is about .30/, ranging from the bargaining power of labor, .26/, to bureaucratization, .32/. The total variance explained in income inequality (\bar{R}^2) is about 55% and ranges from 49% with regard to the share of the bottom three quintiles to 60% with regard to the share of the top 20% of income receivers.

The results of our analysis can be compared only partly with findings in the literature because similar research is lacking. The results with respect to the organizational power distribution are the same as in Bornschier (1978), although there a more complex model was tested. But since we have used the same indicators for the organizational power distribution, the same methodology and only a somewhat different sample, this similarity in the results should not be astonishing. A similar argument applies to government revenues which has been used by Rubinson (1976) who reports very similar results with respect to government revenue.

One should note that the rather strong effect of government revenues, as an indicator of redistribution *potential*, can be demonstrated without identifying the political power constellation. We hypothesize that this is due to the likelihood that, in the global range of variation, a higher share of government in total income is associated with a more equal political power distribution. In fact, there are rather high positive correlations between government revenues and various indicators of "democratic performance" used by Cutright (1967), Jackman (1974), Rubinson and Quinlan (1977), Hewitt (1977), Zwicky (1978), and Ballmer (n.d.). On the other hand, the analysis suggests indirect evidence that the state's control over resources is not necessarily related to lower income inequality. The contrary also could be established through an analysis of covariance. This, we have argued, is related to the interaction effect of high MNC-penetration and scarcity of resources with government revenues. In this case, we have postulated an intervening change in the political power constellation.

We come finally to the concluding evidence for our general hypothesis that MNC-penetration causes a change in the power distribution which is, in turn, related to a more unequal income distribution.

The path diagram to Table 6²⁵ (Figure 3) demonstrates that a very large part of the direct effect of MNC-penetration on personal income inequality is mediated by the

²⁵ Some variables, i.e., SPD, SPT, TREND (for the latter, cf. fn. 14), which have been used for the estimation of path coefficients are not given in the diagram for reasons of easy presentation.

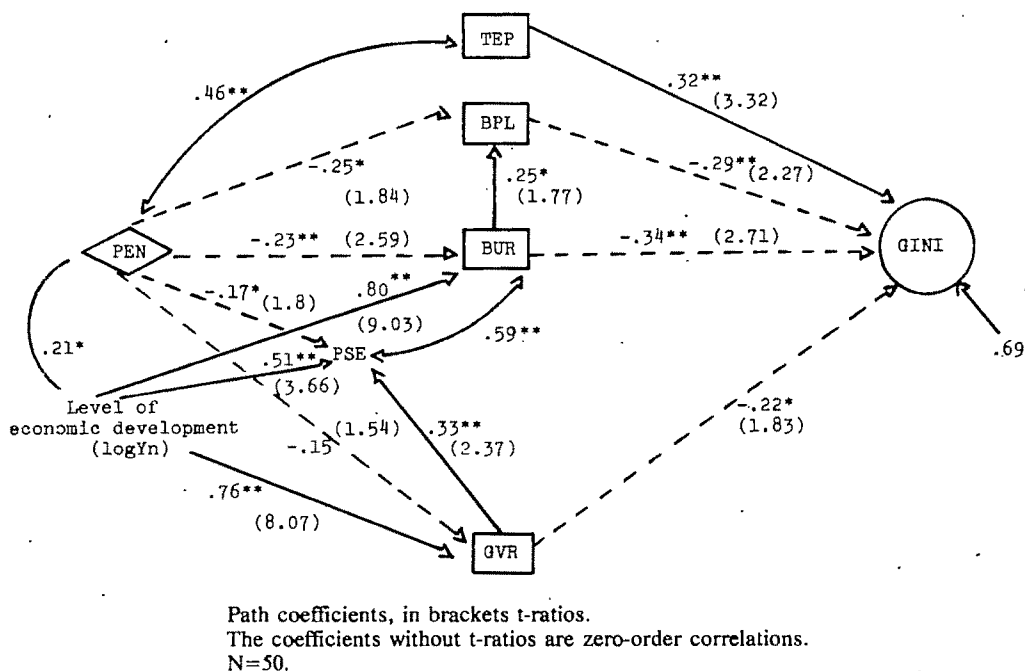

Figure 3. Path Diagram to Table 6

four variables included in the final model. For example the direct path from PEN to Gini has a beta weight of only .09 as compared with .34 in Table 1. MNC-penetration affects negatively the bargaining power of labor (BPL), the distributional change of the labor force towards bureaucratization (BUR) as well as power sharing with expertise (PSE). The latter has not been included in Table 6 because of collinearity. But its effect on some income inequality measures is substantial (cf. Table 2). Whereas these three paths are significant, the negative path from MNC-penetration to government revenue (GVR) is not significant. One could conclude that MNC-penetration primarily affects the state's role for income distribution by changing patterns of expenditure. We would like to point to the relationship between MNC-penetration and concentration of traditional economic power (TEP) which could provide an important hint to one of the socioeconomic and sociopolitical structures prevailing in many countries in which the position of the MNCs is strong (see also above and fn. 13).

We can conclude, then, that the empirical evidence of our research lends pre-

liminary support to the proposition that MNCs are not only likely to perpetuate an unequal power distribution in the agricultural sector, but they are also likely to contribute to a more unequal power distribution in the nonagricultural sector. From the findings of our research, the clearly significant relationship which statistically exists between levels of MNC-penetration and levels of personal income inequality is given a causal explanation.

We feel, however, the need for further research which would deepen and extend the analysis of the suggested transformations in the socioeconomic and in the sociopolitical structures under conditions of high MNC-penetration. Furthermore, an analysis of the theoretically assumed two-way causation between MNC-penetration and income inequality needs time series or, at least, a two-stage least square or an indirect least square estimation procedure. The same applies to the causal interpretation we propose with regard to intervening variables.

Further research also is needed with respect to the finding that the effect of MNC-penetration seems to be stronger for

underdeveloped countries (cf. fn. 6 and Table 5). In addition, the relationship between regional and sectoral inequalities within countries as well as the pattern of spatial location of MNCs should be investigated in future research. Finally, evidence does not support the proposition

that headquarter countries have a more equal income distribution than would be predicted from their level of average surplus. Further research with regard to this complementary hypothesis is necessary.

ITEMS (Continued)

■ REMI CLIGNET (The Variability of Paradigms in the Production of Culture) is Professor of Sociology at Northwestern University. In 1974 he authored *Liberty and Equality in the Educational Process* (Wiley). He is also author of *The Africanization of the Labor Markets* (University of California Press, 1976). He is now working on a study of the sociology of the Arts.

■ ANDREA TYREE (Gaps and Glissandos: Inequality, Economic Development and Social Mobility) is Associate Professor in the Department of Sociology at State University of New York, Stony Brook. Her research interests include comparative stratification and mobility, ascriptive determinants of socioeconomic achievement, and the demographic consequences of infanticide and its demise. MOSHE SEMYONOV is Visiting Haggard Assistant Professor in Sociology at the University of Nebraska-Lincoln. He is investigating the Israeli stratification system (with Andrea Tyree) and is also doing research on places as a dimension of social stratification. ROBERT W. HODGE is currently a Visiting Professor in the Department of Sociology at the University of Southern California. He is on leave from the State University of New York, Stony Brook. He is finishing a monograph on occupational prestige and is continuing the development of a dynamic, econometric model of postwar American society.

■ WILLIAM H. FREY (Central City White Flight) is a Project Director and Affiliate at the Center for Demography and Ecology, Department of Sociology, University of Wisconsin, Madison. His research is concerned with the migration and residential mobility dynamics of intrametropolitan population distribution. For the past three years he has been directing a comparative study of migration and city-suburb redistribution determinants in large metropolitan areas. He is writing a monograph which will report the findings of this study.

■ CLARK MCPHAIL (Mead vs. Blumer) is Associate Professor in the Department of Sociology, Uni-

versity of Illinois. He is conducting quasi-experimental studies of elementary forms of collective behavior. He also is investigating the application of computer-digitizing techniques in the analysis of film records of individual and collective behavior. He is completing a book on collective behavior that will be published by Prentice-Hall. CYNTHIA REX-ROAT is a Ph.D. Candidate in the Department of Sociology at the University of Illinois. She is completing a study of racial differences in wives' labor force participation.

■ PATRICIA A. TAYLOR (Income Inequality in the Federal Civilian Government) is Research Assistant Professor, on leave from Sweet Briar College, and currently at the University of Virginia. She is investigating schooling, training, and occupational change among career civil servants, 1963-1977. In 1978 she coauthored (with Ann Carmel) *A Profile of Hispanic Employment, 1974-1976* (U.S. Government Printing Office).

■ ANDREW COLLVER (Suburban Change and Persistence) is Associate Professor in the Department of Sociology, State University of New York, Stony Brook. His research focuses on studies of housing and community development in the Long Island region. MOSHE SEMYONOV is Visiting Haggard Assistant Professor in the Department of Sociology, University of Nebraska-Lincoln.

■ VOLKER BORNSCHIER (Income Inequality: A Cross-National Study) is Assistant Professor at the Sociological Institute of the University of Zurich. His research interests include world system analysis and social inequality. In 1976 he authored *Wachstum, Konzentration und Multinationalisierung von Industrieunternehmen* (Huber). THANH-HUYEN BALLMER-CAO is Research Fellow at the Sociological Institute of the University of Zurich. She is currently doing research on political participation and on protest and violence.

AMERICAN SOCIOLOGICAL REVIEW

THE COLLECTIVIST ORGANIZATION: AN ALTERNATIVE TO RATIONAL-BUREAUCRATIC MODELS*

JOYCE ROTHSCHILD-WHITT

Cornell University

American Sociological Review 1979, Vol. 44 (August):509-527

During the 1970s the U.S. has witnessed the emergence of a wide range of organizations that explicitly reject the norms of rational-bureaucracy and identify themselves as "alternative institutions" or "collectives." Grounded in an extensive study of the practices of worker collectives, this paper seeks to identify some of the structural commonalities which link these new work organizations and to develop a theoretical framework for understanding them. First, the ideal-type features of collectivist democracy are delineated and contrasted with the characteristic features of bureaucracy. The ideal-type approach allows us to assess these organizations not as failures to achieve bureaucratic standards they do not share, but as efforts to realize wholly different values. Second, constraints and social costs that inhibit the realization of organizational democracy are discussed. It is in the conceptualization of alternative forms of organization that organizational theory has been weakest, and it is here that the experimentation of collectives may broaden our understanding.

This article represents a first approach to a model of collectivist organization, a model that is premised on the logic of substantive rationality rather than formal rationality. To date, theories of organizational action have assumed, explicitly or implicitly, that norms of formal rationality prevail (Thompson, 1967). Indeed, in a modern society they almost always do. This decade, however, has given rise to a wide array of work organizations that self-consciously reject the norms of rational-bureaucracy and identify them-

selves as "alternative institutions." The emergence of these contrabureaucratic organizations calls for a new model of organization that can encompass their alternative practices and aspirations.

Max Weber delineated four types of social action: traditional, affectual, instrumentally rational, and value rational. The first three forms of social action correspond respectively to traditional, charismatic, and legal-rational bases of authority, with each type of authority implying a particular type of organization to implement its aims. But the last type of social action, value-rationality, has no counterpart in his typology of authority and organization. Some recent scholars have begun to look to Weber's missing type, value-rational authority, to understand certain kinds of professional and church organizations (Satow, 1975; Wood, 1978).

A value-rational orientation to social action is marked by a "belief in the value for its own sake . . . independent of its prospects of success" (Weber, 1968:24). It is evidenced by actions that put into practice people's convictions. For Weber (1968:37)

I would like to thank William Foote Whyte, J. Allen Whitt, Robert Stern, Charles Perrow, Carole Pateman, Rosabeth Kanter, Howard Aldrich and the anonymous reviewers of the ASR for valuable comments and suggestions on an earlier draft of this paper. In addition, I would like to acknowledge the support of the New Systems of Work and Participation Program at ILR, Cornell University (NIMH grant #MH 29259-03) during the completion of this work. A previous version of this paper was presented at the Ninth World Congress of Sociology in Uppsala, 1978.

natural law is one of the purest instances of value-rational legitimacy.

The tension between substantive or value-rational action on the one hand, and formal or instrumentally-rational action on the other, was well recognized by Max Weber. For Weber, formal rationality and its main locus of expression in bureaucracy would come to dominate modern society, but it would be continually "confronted by the inevitable conflict between an abstract formalism of legal certainty and [the] desire to realize substantive goals" (Weber, 1954:226). The modern legal order could not exclude a substantive theory of natural law any more than the modern bureaucracy could eliminate all moral values. In Weber's view, the conflict between formal and substantive justice has no ultimate solution (Bendix, 1962:391-438). Nevertheless, in his classic statement on bureaucracy, Weber (1946:196-244) sets forth the characteristics of this mode of organization as if it could eliminate all substantive, non-formal considerations, and contrasts this ideal-type conception of bureaucracy with patrimonial administration. The polar opposite of the monocratic, formal bureaucracy drawn by Weber would be a fully collectivized democracy which turned on principles of substantive rationality.

Just as the ideal of bureaucracy, in its monocratic pure type, is probably not attainable (Mouzelis, 1968); so the ideal of democracy, in its pure and complete form, is probably never achieved. In practice, organizations are hybrids.

This paper aims to develop an ideal-type model of collectivist-democratic organization. It is an attempt to delineate the form of authority and the corresponding mode of organization that follows from value-rational premises. As such it is grounded in observations of counter-bureaucratic organizations which aspire to being "collectives," or in Weberian terms, which have explicitly rejected instrumentally-rational social action in favor of value-rational behavior. The ideal-type approach allows us to understand these new forms of organization, not only in terms of bureaucratic standards they do not share, but in terms of the alternative values they do hold (cf. Kanter

and Zurcher, 1973). Further, the use of an ideal-type permits us to locate actual organizations along a continuum.

Constraints and social costs that inhibit the realization of organizational democracy will be addressed in the latter half of this paper.

Research Settings and Methods

During the 1970s the United States has witnessed an impressive proliferation of what have popularly come to be termed *alternative institutions*. Alternative institutions may be defined in terms of their members' resolve to build organizations which are parallel to, but outside of, established institutions and which fulfill social needs (for education, food, medical aid, etc.) without recourse to bureaucratic authority.

Parallel, oppositional organizations have been created in many service domains—e.g., free medical clinics, free schools, legal collectives, alternative media collectives, food cooperatives, research collectives, communes. Grassroots cooperative businesses are proliferating as well, especially in fields with relatively low capitalization needs such as restaurants, bookstores, clothing manufacture and retail, auto repair, housing construction, alternative energy installation, newspapers, and so forth. They are burgeoning at a remarkable rate. For instance, in 1967 there were about 30 free schools in the United States. By 1973 there were over 800 documented free schools (New Schools Exchange Directory, 1967; 1973). A 1976 directory locates some 5,000 alternative organizations nationwide, and does not even claim to be exhaustive (Gardner, 1976). These collectively owned and managed work enterprises represent one of the enduring legacies of the antiauthority movements of the 1960s.¹

¹ Gardner (1976) estimates that about 1,000 new alternative institutions are being created annually in the U. S. This is his best estimate, but the kind of evidence that would be needed to compute actual rates of creation and of dissolution is not yet available. However, the historical record is instructive. The nineteenth century and the first third of the twentieth century saw at least 700 cases of produc-

Little social scientific research has been devoted to this social development. Some research studies describe one or another of these alternative work organizations, but few point to commonalities which link them. This paper identifies some of the structural commonalities and attempts to develop a general organizational framework of collectivist-democracy in which specific cases may be understood.

The organizational properties formulated in this paper are grounded in comparative data from different types of collectivist organizations. Glaser and Strauss (1967) have argued that theory generated from data, namely, grounded theory, will have more power to predict and explain the subject at hand than will theory arrived at through speculation or logical deduction.

Following the comparative research strategy of Glaser and Strauss (1967), I selected for study five collectivist work organizations that were as varied as possible: a free medical clinic, a legal collective, a food cooperative, a free school, and an alternative newspaper.² All are located in a medium-sized city in California. Although they differ greatly as to the type of product or service they provide, organizational size, funding sources, technology utilized, and so forth, they are unified by the primacy each gives to developing a collectivist-democratic form of organization.

Participant observation was conducted in each of the research settings ranging in duration from six months to two years per

organization. Observational material was amplified by structured interviews with selected members of each of the organizations, with a mean interview time of 2-¼ hours. This was followed by questionnaire surveys to the membership of three of the organizations under study.

Each theoretical point in the paper is grounded in numerous instances from the empirical material. I have tried to select those few that seem most characteristic of the data. Of course, no number of illustrations can ever constitute a "proof." The theoretical formulations in this work should be assessed for their logical consistency, clarity, integration, and especially for the extent to which they are found to be generic properties of collectivist organizations.

The Collectivist Organization: Characteristics

Collectivist-democratic organizations can be distinguished from bureaucratic organizations along at least eight dimensions. Each of these characteristics will be taken up in turn, and a summarizing chart will follow.

Authority.

When we're talking about collectives, we're talking about an embryonic creation of a new society . . . Collectives are growing at a phenomenal rate all over this country. The new structures have outgrown the science of analyzing them. Sociology has to catch up with reality. . . . Collectivism is an attempt to supplant old structures of society with new and better structures. And what makes our's superior is that the basis of authority is radically different. (Staff member, Alternative Paper)

The words of this activist get right to the heart of the matter: authority. Perhaps more than anything else, it is the basis of authority that distinguishes the collectivist organization from any variant of bureaucracy. The collectivist-democratic organization rejects rational-bureaucratic justifications for authority. Here authority resides not in the individual, whether on the basis of incumbency in office or expertise, but in the collectivity as a whole.

This notion stems from the ancient anarchist ideal of "no authority." It is

ers' cooperatives (Aldrich and Stern, 1978). These were in many ways the forerunners of the contemporary wave of collectives and cooperatives discussed in this paper. Historically, cooperatives have come in distinct waves—the 1840s, the 1860s, the 1880s and the 1920s–1930s. Their longevity has varied widely between industries (Aldrich and Stern, 1978). Those of the nineteenth century had a median duration of less than ten years, while more than half of the worker cooperatives of the 1920s and 1930s (particularly in the plywood industry and in the refuse collection industry) are still in operation today (Jones, 1979). Since the current wave of collectives is largely a post-1970 phenomenon and is still on the rise, it is too early to say how long it will last.

² All persons and organizations have been given fictitious names in this paper. For a more detailed account of the research sites and methods see Rothschild-Whitt (1976; 1978).

premised on the belief that social order can be achieved without recourse to authority relations (Guerin, 1970). Thus it presupposes the capacity of individuals for self-disciplined, cooperative behavior. Indeed, collectivist organizations routinely emphasize these aspects of human beings. Like the anarchists, their aim is not the transference of power from one official to another, but the abolition of the pyramid in toto: organization without hierarchy.

An organization cannot be comprised of a collection of autonomous wills, each pursuing its own personal ends. Some decisions must be binding on the group.

Decisions become authoritative in collectivist organizations to the extent that they derive from a process in which all members have the right to full and equal participation. This democratic ideal, however, differs significantly from conceptions of "democratic bureaucracy" (Lipset et al., 1962), "representative bureaucracy" (Gouldner, 1954), or even representative democracy. In its directly democratic form, it does not subscribe to the established rules of order and protocol. It does not take formal motions and amendments, it does not usually take votes, majorities do not rule, and there is no two-party system. Instead there is a "consensus process" in which all members participate in the *collective* formulation of problems and *negotiation of decisions*.³ All major policy issues, such as hiring, firing, salaries, the division of labor, the distribution of surplus, and the shape of the final product or service, are decided by the collective as a whole. Only decisions which appear to carry the consensus of the group behind them, carry the weight of moral authority. Only these decisions, changing as they might with the ebb and flow of sentiments in the group, are taken as binding and legitimate. These organizations are collectively-controlled

by their members or workers: hence the name *collectivist* or *collectivist-democratic* organization.

In Weberian terms, we are concerned here with organizations which aspire and claim to be free of *Herrschaft*.⁴ They are organizations without domination in that ultimate authority is based in the collectivity as a whole, not in the individual. Individuals, of course, may be delegated carefully circumscribed areas of authority, but authority is delegated and defined by the collectivity and subject to recall by the collectivity.

Rules. Collectivist organizations also challenge the bureaucratic conception that organizations should be bound by a formally established, written system of rules and regulations. Instead, they seek to minimize rule use. But, just as the most bureaucratic of organizations cannot anticipate, and therefore cannot circumscribe, *every* potential behavior in the organization, so the alternative organization cannot reach the theoretical limit of *zero* rules. Collectivist organizations, however, drastically can reduce the number of spheres of organizational activity that are subject to explicit rule governance.

In the most simple of the collectivist organizations in this study, the free high school, only one explicit organizational rule was formulated: no dope in school. This rule was agreed upon by a plenary meeting of the school's students and staff primarily because its violation was perceived to threaten the continued existence

³ As organizations grow beyond a certain size they are likely to find purely consensual processes of decision making inadequate, and may turn to direct voting systems. Other complex, but nevertheless democratic, work organizations may sustain direct democracy at the shop floor level, while relying upon elected representative systems at higher levels of the organization (cf. Edelstein and Warner, 1976).

⁴ Actually, Weber did recognize the possibility of directly democratic organization, but he dealt with this only incidentally as a marginal type case (Weber, 1968:948-52; 289-92). Although Weber's three types of legitimate domination were meant to be comprehensive, both in time and in substance, as Mommsen (1974:72-94) points out, it is difficult to find an appropriate place for modern plebiscitarian democracy in Weber's scheme. Weber did come to advocate the "plebiscitarian leader-democracy," but this was a special version of charismatic domination (Mommsen, 1974:113). He did not support "democracies without leadership" (*fuererlose Demokratien*) which try to minimize the domination of the few over the many because organization without *Herrschaft* appeared utopian to him (Mommsen, 1974:87). Thus it is difficult to identify the acephalous organizations of this study with any of Weber's three types of authority.

of the school. Other possible rules also were discussed at the Free School, rules that might seem self-evident in ordinary schools such as "each student should take X number of classes" or "students are required to attend the courses for which they are registered," but these did not receive the consensual backing of the school's members.

In place of the fixed and universalistic rule use which is the trademark of bureaucracy, operations and decisions in alternative organizations tend to be conducted in an ad hoc manner. Decisions generally are settled as the case arises, and are suited to the peculiarities of the individual case. No written manual of rules and procedures exists in most collectives, though norms of participation clearly obtain. While there is little attempt to account for decisions in terms of literal rules, concerted efforts are made to account for decisions in terms of substantive ethics. This is like Weber's (1968:976-8) *Kadi* justice and far removed from the formal justice that informs rational-bureaucratic action.

One of the chief virtues of extensive rule use in bureaucracy is that it permits predictability and appeal of decisions. The lack of universalistic standards in prebureaucratic modes of organization invited arbitrary and capricious rule. In bureaucracy decisions could be calculated and appealed on the basis of their correspondence to the written law. In collectivist organizations, however, decisions are not necessarily arbitrary. They are based on substantive values (e.g., equality) applied consistently, if not universally. This permits at least some calculability on the basis of knowing the substantive ethic that will be invoked in a particular situation.

Social control. From a Weberian point of view, organizations are tools. They are instruments of power for those who head them. But what means does the bureaucracy have of ensuring that lower-level personnel, people who are quite distant from the centers of power, effectively will understand and implement the aims of those at the top? This issue of social control is critical in any bureaucracy. Perrow (1976) examines three types of social control mechanisms in bureaucracies: direct

supervision, standardized rules, and selection for homogeneity. The first type of control, direct supervision, is the most obvious. The second is far less obtrusive, but no less effective: standardized rules, procedures, and sanctions. Gouldner (1954) showed that rules can substitute for direct supervision. This allows the organization considerable decentralization of everyday decision making, and even the appearance of participation, for the *premises* of those decisions have been carefully controlled from the top. Decentralized decision making, when decisional premises are set from the top via standardized rules, may be functionally equivalent to centralized authority (cf. Blau, 1970; Bates, 1970; Perrow, 1976).

Collectivist organizations generally refuse to legitimate the use of centralized authority or standardized rules to achieve social control. Instead, they rely upon personalistic and moralistic appeals to provide the primary means of control, as Swidler (1979) demonstrates in her examination of free schools. In Etzioni's (1961) terms, compliance here is chiefly normative. One person appeals to another, "do X for me," "do X in the interest of equality," and so forth.

The more homogeneous the group, the more such appeals can hold sway. Thus, where personal and moral appeals are the chief means of social control, it is important, perhaps necessary, that the group select members who share their basic values and world view. All five of the alternative organizations in this study tried to do that. At the Law Collective, for instance, I asked how they decide whether to take in a new member:

They have to have a certain amount of past experience in political work . . . [,] something really good and significant that checks out Secondly, they have to share the same basic assumptions as far as politics goes and they have to be willing to accept the collective way of doing things

Such recruitment criteria are not at all uncommon or hidden in alternative work organizations.

In Perrow's (1976) terms alternative organizations eschew first- and second-level controls, but accept third-level controls. Third-level controls are the most

subtle and indirect of all: selection of personnel for homogeneity. On this level social control may be achieved by selecting for top managerial positions only people who "fit in"—people who read the right magazines, go to the right clubs, have the right style of life and world view. This is also true in collectivist organizations. Where people are expected to participate in major decisions (and this means *everyone* in a collective and high-level managers in a bureaucracy) consensus is crucial, and people who are likely to challenge basic assumptions are avoided. A person who reads the *Wall Street Journal* would be as suspect in applying for a position at the Law Collective, as a person who reads the *New Left Review* would be at ITT. Both kinds of organizations utilize selection for homogeneity as a mechanism for social control.

Social relations. Impersonality is a key feature of the bureaucratic model. Personal emotions are to be prevented from distorting rational judgements. Relationships between people are to be role-based, segmental, and instrumental. Collectivist organizations, on the other hand, strive toward the ideal of community. Relationships are to be wholistic, affective, and of value in themselves. The search for community may even become an instance of goal displacement, as when, for example, a free school comes to value community so highly that it loses its identity as a school and becomes a commune (see, e.g., Kaye, 1972).

Recruitment and advancement. Bureaucratic criteria for recruitment and advancement are resisted in the collectivist organization. Here employment is not based on specialized training or certification, nor on any universalistic standard of competence. Instead, staff are generally recruited and selected by collectives on the basis of friendship and social-political values. Personality attributes that are seen as congruent with the collectivist mode of organization, such as self-direction and collaborative styles, also may be consciously sought in new staff (see, e.g., Torbert, 1973).

Employment does not constitute the beginning of a career in collectivist organizations in the usual sense, for the collec-

tive does not provide a life-long ladder to ever-higher positions. Work may be volunteer or paid, and it may be part-time or full-time or even 60 hours per week, but it is not conceptualized as a career. Bureaucratic career advancement (based on seniority and/or achievement) is not a meaningful concept in collective work organizations, for there is no hierarchy of offices. Therefore, there can be no individual *advancement* in positional rank (though there may be much change in positions).

Collectivist work organizations generally recruit competent and skilled personnel even though their selection criteria explicitly emphasize friendship networks, political values, and personality traits. To illustrate, during the year in which the Free Clinic was observed, four full-time staff positions were filled, and between nine and 65 applications were received for each position. Yet each of the four positions went to a friend of present staff members. The relevant attributes cited most frequently by the staff making these decisions were: articulation skills, ability to organize and mobilize people, political values, self-direction, ability to work under pressure, friendship, commitment to the organization's goals, cooperative style, and relevant experience. These selection criteria are typical of alternative organizations. In spite of their studied neglect of *formal* criteria of competence (e.g., certification), alternative organizations often attract highly qualified people.⁵ In many ways, their selection criteria are well suited to their needs for multitasking and committed personnel who can serve a variety of administrative and task-oriented functions and who are capable of managing the organization in cooperation with others.

Incentive structure. Organizations use different kinds of incentives to motivate participation. Most bureaucratic workplaces emphasize remunerative incentives and few employees could be expected to donate their services if their paychecks

⁵ A dissertation conducted in the San Francisco area found that free school teachers there have higher degrees from more prestigious universities than their public school counterparts (McCauley, 1971:148).

were to stop. Collectivist organizations on the other hand, rely primarily on purposive incentives (value fulfillment), secondarily on solidary incentives such as friendship, and only tertiarily on material incentives (Clark and Wilson, 1961). According to Etzioni (1961), this kind of normative compliance system tends to generate a high level of moral commitment to organization. Specific structural mechanisms which produce and sustain organizational commitment are identified by Kanter (1972a). Because collectivist work organizations require a high level of commitment, they tend to utilize some of these mechanisms as well as value-purposive incentives to generate it. Indeed, work in collectives is construed as a labor of love, and members may pay themselves very low salaries and may expect each other to continue to work during months when the organization is too poor to afford their salaries.

Alternative organizations often appeal to symbolic values to motivate people to join and to participate actively. The range of these values is considerable. At the Free Clinic, for instance, a member describes motivation:

Our volunteers are do-gooders. . . . They get satisfaction from giving direct and immediate help to people in need. This is why they work here.

While at the Alternative Newspaper, the following is more illustrative:

Our motives were almost entirely political. We were moving away from a weathermen type position, toward the realization that the revolution will be a very gradual thing. . . . We wanted to create a base for a mass left. To activate liberals and open them up to left positions. To tell you the truth, the paper was conceived as a political organ.

At the Food Co-op it is the value of community that is most stressed, and the Co-op actively helps to create other community-owned and controlled institutions in its locale.

However, we should guard against an overly idealistic interpretation of participation in alternative organizations. In these organizations, as much as any, there exists an important *coalescence of material and ideal interests*. Even volunteers in

these organizations, whose motives on the face of it would appear to be wholly idealistic, also have material incentives for their participation.

For example, staff members at the Free Clinic suspect that some volunteers donate their time to the clinic "only to look good on their applications to medical school." Likewise, some of the college students who volunteered to teach at the Free School believed that in a tight market, this would improve their chances of getting a paid teaching job. And, for all the talk of community at the Food Co-op, many members undoubtedly joined simply because the food was cheaper. Because material gain is not part of the acceptable vocabulary of motives in these organizations, public discussion of such motives is suppressed.

Nonetheless, for staff members as well as for volunteers, material incentives coalesce with moral incentives. At the Law Collective, for instance, legal workers often used their experience there to pursue the bar, since California law allows eligibility for the bar through the alternative means of apprenticing under an attorney for three years. At the Alternative Newspaper, a few staff members confided that they had entered the paper to gain journalistic experience.

Yet members of alternative institutions often deny the existence of material considerations and accept only the idealistic motivations. In the opinion of one long-time staffer at the Alternative Paper:

I don't think anyone came for purely journalistic purposes, unless they're masochists. I mean it doesn't pay, the hours are lousy, and the people are weird. If you want professional journalistic experience you go to a straight paper.

In many ways, she is right: Alternative institutions generally provide woefully inadequate levels of remuneration by the standards of our society. But, it does not impugn the motives of participants to recognize that these organizations must provide some material base for their members if they are to be alternative places of employment at all.

At the Free Clinic full-time staff were all paid \$500 per month during 1974-1975, at the Law Collective they were paid a base

of \$250 per month plus a substantial supplement for dependents, and at the Alternative Paper they received between \$150 and \$300 per month, in accordance with individual "needs." These pay levels were negotiated in open discussion of the collectives as a whole, as were decisions regarding the entire labor process. If these wage levels appear exploitative, it is a case of self-exploitation. It is the subsistence wage levels which permit the young organization to accumulate capital and to reinvest this surplus in the organization rather than paying it out in wages. This facilitates the growth of the organization and hastens the day when it may be able to pay higher salaries.⁶

Many collectives have found ways to help compensate for the meager salaries they pay their members. The Law Collective stocked food so that members could eat at least a meal or two per day at the office for free. The collective also maintained a number of cars that its members could share, thereby eliminating the need for private automobile ownership. Free Clinic staff decided to allow themselves certain fringe benefits to compensate for what they regarded as underpaid work: two weeks of paid vacation time each year, plus two additional weeks of unpaid vacation (if desired); one day off every other week; and the revised expectation that staff would regularly work a 28-30 rather than 40-hour week. But these are compensations or supplements for a generally poor income, and like income, they do not motivate people to work in alternative organizations, they only make work there possible.

First and foremost, people come to work in an alternative organization because it offers them substantial control over their work. Collective control means

that members can structure both the product of their work and the work process in congruence with their ideals. Hence, the work is purposeful to them. It is not infrequently contrasted with alienating jobs that they have had, or imagine, in bureaucracies:

A straight paper would have spent a third of a million dollars getting to where we are now and still wouldn't be breaking even. We've gotten where we are on the sweat of our workers. They've taken next to no money when they could have had 8,000 to 15,000 in straight papers doing this sort of job. . . . They do it so they can be their own boss. So they can own and control the organization they work in. So they can make the paper what *they* want it to be. . . . (interview, member of Alternative Newspaper)

Social stratification. In the ideal-type bureaucracy, the dimensions of social stratification are consistent with one another. Specifically, social prestige and material privilege are to be commensurate with one's positional rank, and the latter is the basis of authority in the organization. Thus, a hierarchical arrangement of offices implies an isomorphic distribution of privilege and prestige. In this way, hierarchy institutionalizes (and justifies) inequality.

In contrast, egalitarianism is a central feature of the collectivist-democratic organization. Large differences in social prestige or privilege, even where they are commensurate with level of skill or authority in bureaucracy, would violate this sense of equity. At the Free Clinic, for instance, all full-time staff members were paid equally, no matter what skills or experience they brought to the clinic. At the Law Collective and Alternative Newspaper pay levels were set "to each according to his need." Here salaries took account of dependents and other special circumstances contributing to need, but explicitly excluded considerations of the worth of the individual to the organization. In no case I observed was the ratio between the highest pay and the lowest pay greater than two to one.

In larger, more complex, democratic organizations wages are still set, and wage differentials strictly limited, by the collectivity. For example, in the 65 production

⁶ The self-exploitation common in collectivist organizations and the justifications for it (e.g., autonomy, control over the workplace, self-expression in work) are similar to that of the small entrepreneur. It may be that as economic concentration and oligopolistic control over markets renders traditional entrepreneurial activity obsolete, collectively-owned enterprises may grow. For, in many ways, collectivist efforts evoke the old entrepreneurial spirit, but today it may require the intense work and self-sacrifice of many people rather than just one to make a fledgling enterprise viable.

cooperatives that constitute the Mondragón system in Spain pay differentials are limited to a ratio of three to one in each firm (Johnson and Whyte, 1977). In the worker-owned and managed refuse collection firms in San Francisco, the differential is only two to one, or less (Russell, et al., 1979; Perry, 1978). Schumacher (1973:276) reports a seven to one ratio between the highest and the lowest paid at Scott Bader, a collectively-owned firm in England. The cooperatively-owned plywood mills in the Pacific Northwest pay their members an equal wage (Bernstein, 1976:20-1). By comparison, the wage differential tolerated today in Chinese work organizations is 4:1; in the United States it is about 100:1.

Prestige, of course, is not as easily equalized as is pay. Nonetheless, collectivist organizations try in a variety of ways to indicate that they are a fraternity of peers. Through dress, informal relations, task sharing, job rotation, the physical structure of the workplace, equal pay, and the collective decision-making process itself—collectives convey an equality of status. As Mansbridge (1977) observes of collectives, reducing the sources of status inequality does not necessarily lead to the magnification of trivial differences. Likewise, decreasing the material differentials between individuals in a collectivist organization does not ordinarily produce a greater emphasis on status distinctions.

Differentiation. A complex network of specialized, segmental roles marks any bureaucracy. Where the rules of scientific management hold sway, the division of labor is maximized: jobs are subdivided as far as possible. Specialized jobs require technical expertise. Thus, bureaucracy ushers in the ideal of the specialist-expert and defeats the cultivated, renaissance man of an earlier era (Weber, 1946:240-4).

In contrast, differentiation is minimized in the collectivist organization. Work roles are purposefully kept as general and wholistic as possible. They aim to eliminate the division of labor that separates intellectual workers from manual workers, administrative tasks from performance tasks. Three means are commonly utilized toward this end: role rotation,

teamwork or task sharing, and the diffusion or demystification of specialized knowledge through internal education.

Ideally, universal competence (of the collective's members) would be achieved in the tasks of the organization. It is the *amateur-factotum* then who is ideally suited for the collectivist organization. In the completely democratized organization, everyone manages and everyone works. This may be the most fundamental way in which the collectivist mode of organization alters the social relations of production.⁷

This alteration in the division of labor is perhaps best illustrated by the Free School, an organization in which administrative functions were quite simple, and undifferentiated. The Free School had no separate set of managers to administer the school. Whenever administrative tasks were recognized, "coordination meetings" were called to attend to them; these were open to all interested teachers and students. Coordinators were those who were willing to take responsibility for a particular administrative task (e.g., planning curriculum, writing a press release, organizing a fund-raiser). A coordinator for one activity was not necessarily a coordinator for another project. Further, the taking on of administrative tasks was assumed to be a part-time commitment which could be done along side of one's other responsibilities. Coordinators, then, were *self-selected*, *rotated*, and *part-time*. No one was allowed to do administration exclusively. By simplifying administration and opening it up to the membership-at-large, the basis and pretense of special expertise was eliminated.

The school even attempted to break down the basic differentiation between students and staff, regarding students not as clients but as members with decision-

⁷ Industrial organizations in China have implemented similar changes in the division of labor. These were considered an essential part of transforming the social relations of production. Their means for reducing the separation of intellectual work from manual work and administration from performance tasks were similar to those used by the alternative work organizations reported in this paper: team work, internal education, and role rotation. For specific points of comparison see Bettelheim (1974) and Whyte (1973).

making rights and responsibilities. The Free Clinic also tried to integrate its clients into the organization. For instance, it created spaces on its board of directors for consumers of medical care and recruited many of its volunteers from the ranks of its patients.

Most alternative organizations are more complex than the Free School. They cannot assume that everyone in the organization knows how (or would want to know how) to do everything. Thus, they must develop explicit procedures to achieve universal competence. Such procedures, in effect, attack the conventional wisdom of specialized division of labor and seek to create more integrated, multifaceted work roles.

The Alternative Newspaper, for example, utilizes task sharing (or team work), apprenticeships, and job rotations toward this end. Instead of assigning one full-time person to a task requiring one person, they would be more likely to assign a couple of people to the task part-time. Individuals' allocations of work often combine diverse tasks, such as 15 hours writing, 15 hours photography, and 10 hours production. In this way, the distribution of labor combines satisfying tasks with more tedious tasks and manual work with intellectual work. People do not enter the paper knowing how to do all of these jobs, but the emphasis on task sharing allows the less experienced to learn from the more experienced. Likewise, if a task has few people who know how to perform it well, a person may be allocated to apprentice with the incumbent. Internal education is further facilitated by occasional job rotations. Thus, while the Alternative Paper must perform the same tasks as any newspaper, it attempts to do so without permitting the usual division of labor into specialties or its concomitant monopolization of expertise.

Minimizing differentiation is difficult and time consuming. The Alternative Paper, for instance, spent a total of fifteen hours and forty minutes of formal meeting time and many hours of informal discussion in planning one systematic job rotation. Attendance at the planning meetings was 100%. The time and priority typically devoted to internal education in collec-

tivist organizations makes sense only if it is understood as part of a struggle against the division of labor. The creation of an equitable distribution of labor and wholistic work roles is an essential feature of the collectivist organization.

Table 1 summarizes the ideal-type differences between the collectivist mode of organization and the bureaucratic.⁸ Democratic control is the foremost characteristic of collectivist organization, just as hierarchal control is the defining characteristic of the smoothly-running bureaucracy. Thus, collectivist-democratic organization would transform the social relations to production. Bureaucracy maximizes formal rationality precisely by centralizing the locus of control at the top of the organization; collectives decentralize control such that it may be organized around the alternative logic of substantive rationality.

Imperfect Democracy: Constraints and Social Costs

Various constraints limit the actual attainment of democracy, and even to the extent that the collectivist-democratic ideal is achieved, it may produce social costs that were unanticipated. This section outlines some of the more important of these constraints and social costs.

Judgments about the relative importance of the listed social costs are intri-

⁸ The eight dimensions discussed here are clearly interrelated, a point not explored herein. However, there is evidence from bureaucracies that they are also somewhat independent (Hall, 1963). That is, an organization may be highly collectivist on one dimension but not so on another. The interrelationships between these variables may be elusive. For instance, of seven propositions offered by Hage (1965) in an axiomatic theory of organizations, six could be supported by the organizations in this study. One, however, that higher complexity produces lower centralization, was contradicted by the evidence of this study, although it has received empirical support in studies of social service bureaucracies (Hage, 1965; Hage and Aiken, 1970). Hage suggests that relationships in organizational theory may be curvilinear: when organizations approach extreme scores the extent relationships may no longer hold or may actually be reversed. This is an important limitation to bear in mind, especially as we begin to consider organizations, such as the ones in this study, that are by design extreme on all eight continua proposed in this model.

Table 1. Comparisons of Two Ideal Types of Organization

Dimensions	Bureaucratic Organization	Collectivist-Democratic Organization
1. Authority	1. Authority resides in individuals by virtue of incumbency in office and/or expertise; hierarchal organization of offices. Compliance is to universal fixed rules as these are implemented by office incumbents.	1. Authority resides in the collectivity as a whole; delegated, if at all, only temporarily and subject to recall. Compliance is to the consensus of the collective which is always fluid and open to negotiation.
2. Rules	2. Formalization of fixed and universalistic rules; calculability and appeal of decisions on the basis of correspondence to the formal, written law.	2. Minimal stipulated rules; primacy of ad hoc, individuated decisions; some calculability possible on the basis of knowing the substantive ethics involved in the situation.
3. Social Control	3. Organizational behavior is subject to social control, primarily through direct supervision or standardized rules and sanctions, tertiary through the selection of homogeneous personnel especially at top levels.	3. Social controls are primarily based on personalistic or moralistic appeals and the selection of homogeneous personnel.
4. Social Relations	4. Ideal of impersonality. Relations are to be role-based, segmental and instrumental.	4. Ideal of community. Relations are to be wholistic, personal, of value in themselves.
5. Recruitment and Advancement	5.a. Employment based on specialized training and formal certification. 5.b. Employment constitutes a career; advancement based on seniority or achievement.	5.a. Employment based on friends, social-political values, personality attributes, and informally assessed knowledge and skills. 5.b. Concept of career advancement not meaningful; no hierarchy of positions.
6. Incentive Structure	6. Remunerative incentives are primary.	6. Normative and solidarity incentives are primary; material incentives are secondary.
7. Social Stratification	7. Isomorphic distribution of prestige, privilege, and power; i.e., differential rewards by office; hierarchy justifies inequality.	7. Egalitarian; reward differentials, if any, are strictly limited by the collectivity.
8. Differentiation	8.a. Maximal division of labor: dichotomy between intellectual work and manual work and between administrative tasks and performance tasks. 8.b. Maximal specialization of jobs and functions; segmental roles. Technical expertise is exclusively held: ideal of the specialist-expert.	8.a. Minimal division of labor: administration is combined with performance tasks; division between intellectual and manual work is reduced. 8.b. Generalization of jobs and functions; wholistic roles. Demystification of expertise: ideal of the amateur factotum.

cately tied to cultural values. Alternative organizations may be mistakenly assessed when seen through the prism of the norms and values of the surrounding bureaucratic society.

Time. Democracy takes time. This is one of its major social costs. Two-way communication structures may produce higher morale, the consideration of more

innovative ideas, and more adaptive solutions to complex problems, but they are undeniably slow (Leavitt, 1964:141-50). Quite simply, a boss can hand down a bureaucratic order in a fraction of the time it would take a group to decide the issue democratically.

The time absorbed by meetings can be extreme in democratic groups. During the

early stages of the Alternative Newspaper, for instance, three days out of a week were taken up with meetings. Between business meetings, political meetings, and "people" meetings, very little time remained to do the tasks of the organization. Members quickly learn that this is unworkable. Meetings are streamlined. Tasks are given a higher priority. Even so, constructing an arrangement that both saves time and ensures effective collective control may prove difficult: Exactly which meetings are dispensable? What sorts of decisions can be safely delegated? How can individuals still be held accountable to the collectivity as a whole? These sorts of questions come with the realization that there are only 24 hours in a day.

There is a limit, however, to how streamlined collectivist meetings can get. In the end, commitment to decisions and their implementation can only be assured in collectives through the use of the democratic method. Unilateral decisions, albeit quicker, would not be seen as binding or legitimate. With practice, planning and self-discipline, groups can learn to accomplish more during their meeting time. But once experience is gained in how to conduct meetings, time given to meetings appears to be directly correlated with level of democratic control. The Free Clinic, for instance, could keep its weekly staff meetings down to an average of one hour and fifteen minutes only by permitting individual decision making outside-the-meeting to a degree that would have been unacceptable to members of the Alternative Paper, where a mean of four hours was given over to the weekly staff meeting.

Homogeneity. Consensus, an essential component of collectivist decision making, may require from the outset substantial homogeneity. To people who would prefer diversity, this is a considerable social cost.

Bureaucracy may not require much homogeneity, partly because it does not need the moral commitment of its employees. Since it depends chiefly on remunerative incentives to motivate work and since in the end it can command obedience to authority, it is able to unite the energies of diverse people toward

organizational goals. But, in collectives where the primary incentives for participation are value-purposive and the subordinate-superordinate relation has been delegitimated, moral commitment becomes necessary. Unified action is possible only if individuals substantially agree with the goals and processes of the collective. This implies a level of homogeneity (in terms of values) unaccustomed and unnecessary in bureaucracy.⁹

Consequently, collectivist organizations also tend to attract a homogeneous population in terms of social origins. At the Alternative Paper full-time staff members came from families where the mean parental income was about \$29,000. A random sampling of the general membership of the Food Co-op (consisting of 1,100 people) reveals an average parental income of \$19,500, while the most active members of the Co-op, the staff and board, show a mean parental income of \$46,000. In addition to being of financially privileged origins, people in alternative organizations tend to come from well-educated families. In both of the above organizations, over half of the mothers had at least some college; fathers on the average had acquired some graduate or professional training beyond the B.A. Thus, the need for substantial agreement on the values, goals and processes of the collective, in effect, has limited their social base. This is an important constraint to members who would like to

⁹ Organizations which are homogeneous in this sense probably register substantial agreement over organizational goals (or what Thompson and Tuden [1959] call "preferences about outcomes"), but register considerable disagreement about how to get there ("beliefs about causation"). In such cases, Thompson and Tuden predict that organizations will reach decisions by majority judgment. A collegium type of organization, they maintain, is best suited for solving judgmental problems. This would require all members to participate in each decision, route pertinent information about causation to each member, give each member equal influence over the final choice, require fidelity to the group's preference structure, and designate as ultimate choice the judgment of the majority. On all but the last point they correctly describe collectivist work organizations. Further, as they point out, the social science literature does not contain models of this type of organization as it does for bureaucracy (Thompson and Tuden, 1959:200).

broaden the base of their social movement.

This is also an important constraint in organizations with heterogeneous populations of employees. For example, International Group Plans, a Washington, D.C. insurance company, is in the process of trying to democratize its ownership and governance structure (Zwerdling, 1977). To many of its employees who do not share collectivist values, democratization may only mean added time and responsibility; and they may wish to retain the traditional separation of managers and workers.

To guard against this problem and to ensure that all members profess collectivist values, alternative organizations tend to recruit very selectively. The Law Collective, for instance, instituted a probationary period of six months on top of its careful selection procedures.

In sum, cultural homogeneity makes reaching and abiding by a consensus easier, but it may constrain the social base of collectivist organization.

Emotional intensity. The familial, face-to-face relationships in collectivist organizations may be more satisfying than the impersonal relations of bureaucracy, but they are also more emotionally threatening. The latter may be experienced as a social cost of participatory organization.

Interpersonal tension is probably endemic in the directly democratic situation, and members certainly perceive their workplaces to be emotionally intense. At the Law Collective a member warns that "plants die here from the heavy vibes." At the Alternative Newspaper I observed headaches and other signs of tension before meetings in which divisive issues would be raised. A study of the New England town meeting found citizens reporting headaches, trembling, and even fear for one's heart as a result of the meetings. Altogether, a quarter of the people in a random sample of the town spontaneously suggested that the conflictual character of the meetings disturbed them (Mansbridge, 1979; 1973).

To allay these fears of conflict, townspeople utilize a variety of protective devices: criticism is concealed or at least softened with praise, differences of opin-

ion are minimized in the formulation of a consensus, private jokes and intimate communications are used to give personal support during the meetings. Such avoidance patterns have the unintended consequence of excluding the not fully-integrated member, withholding information from the group, and violating the norms of open participation. Further, these same fears of conflict and avoidance patterns are in evidence even in groups which are highly sensitive to these issues and in which many members have been trained in group process (Mansbridge, 1979).

The constancy of such feelings in all of the groups I observed suggests that they are rooted in the structure of collectivist decision making. Although participants generally attribute conflict and avoidance to the stubborn, wrongheaded, or otherwise faulty character of others, it may be an inherent cost of participatory-democracy.

Structural tensions inherent in collectivist organization render conflict difficult to absorb. First, the norm of consensual decision making in collectives makes the possibility of conflict all the more threatening because unanimity is required (where a majoritarian system can institutionalize and absorb conflicting opinions). Second, the intimacy of face-to-face decision making personalizes the ideas that people espouse and thereby makes the rejection of those ideas harder to bear (while a more formal bureaucratic system, to the extent that it disassociates an idea from its proponent, makes the criticism of ideas less interpersonally risky).

Nondemocratic individuals. Due to prior experiences, many people are not very well-suited for participatory-democracy. This is an important constraint on its development.

The major institutions of our society, such as educational institutions, combine to reinforce ways of thinking, feeling, and acting that are congruent with capitalist-bureaucratic life and incompatible with collectivist orientations. For example, Jules Henry (1965) has shown how the norms of capitalist culture become the hidden curriculum of the school system. Even at the preschool level, the

qualities of the bureaucratic personality are unconsciously, but nevertheless consistently, conveyed to children (Kanter, 1972b). In fact, Bowles and Gintis (1976) argue that the chief function of the entire educational apparatus is to reproduce the division of labor and hierarchal authority of capitalism.

In the face of these behavior-shaping institutions, it is very difficult to sustain collectivist personalities. It is asking, in effect, that people in collectivist organizations constantly shift gears, that they learn to act one way inside their collectives and another way outside. In this sense, the difficulty of creating and sustaining collectivist attributes and behavior patterns results from a cultural disjuncture. It derives from the fact that alternative work organizations are as yet isolated examples of collectivism in an otherwise capitalist-bureaucratic context. Where they are not isolated, that is, where they are part of an interlocking network of cooperative organizations, such as the Mondragón system in Spain (Johnson and Whyte, 1977) this problem is mitigated.

In their present context the experience of the alternative institutions has shown that selecting people with collectivist attitudes does not guarantee that these attitudes will be effectively translated into cooperative behavior (see, e.g., Swidler, 1976; Taylor, 1976; Torbert, 1973).

Nevertheless, a number of recent case studies of democratic workplaces, one of the worker-owned refuse collection companies (Russell et al., 1979; Perry, 1978) and one of a women's health collective (Bart, 1979), reveal that the experience of democratic participation can alter peoples' values, the quality of their work, and ultimately, their identities. In a comparative examination of many cases of workers' participation, Bernstein (1976:91-107) finds democratic consciousness to be a necessary element for effective workers' control to take place.

Fortunately, the solution to this problem of creating democratic consciousness (and behavior) may be found in the democratic method itself. In this vein, Pateman has amassed a considerable body of evidence from research on political socialization in support of the classical arguments

of Rousseau, Mill, and Cole. She concludes:

We do learn to participate by participating and . . . feelings of political efficacy are more likely to be developed in a participatory environment. . . . The experience of a participatory authority structure might also be effective in diminishing tendencies toward non-democratic attitudes in the individual. (1970:105)

Elden (1976) provides further empirical support for Pateman's position that participation enhances feelings of political efficacy. If bureaucratic organizations thwart the sense of efficacy that would be needed for active participation in democracy (see Blumberg, 1973:70-138), then collectivist-democratic organizations must serve an important educative function, if they are to expand beyond their currently limited social base.¹⁰

Environmental constraints. Alternative organizations, like all organizations, are subject to external pressures. Because they often occupy an adversary position vis-à-vis mainstream institutions, such pressures may be more intense. Extra-organizational constraints on the devel-

¹⁰ To Pateman (1970) the theory of participatory-democracy rises or falls on this educative function. But other social scientists (see especially, Argyris, 1974) remain unconvinced that participation in collectivist-democratic processes of organization can produce the desired changes in peoples' behavior. For Argyris, unilateral, defensive, closed, mutually protective, non-risk-taking behavior, what he calls Model I behavior, is nearly universal: it permeates not only western bureaucracies but also counter-bureaucracies such as alternative schools as well as collectivist organizations in contemporary China and Yugoslavia. Change in organizational behavior cannot be expected to follow from fundamental change in the mode of production; for Model I behavior is rooted in the pyramidal values of industrial culture and in the finiteness of the human mind as an information processing machine in the face of environmental complexity.

Contrarily, I am arguing that where people do not have participatory habits, it is because they generally have not been allowed any substantive control over important decisions. Nondemocratic (pyramidal) habits are indeed a problem for democratic groups, but they are not a problem that a redistribution of power could not resolve. Admittedly, the evidence is not yet conclusive on this issue, but much of it does indicate that the practice of democracy itself develops the capacity for democratic behavior among its participants (see especially, Blumberg, 1973; Pateman, 1970).

opment of collectivist organizations may come from legal, economic, political, and cultural realms.

It is generally agreed among free schoolers, for instance, that building and fire codes are most strictly enforced for them (Kozol, 1972; Graubard, 1972). This is usually only a minor irritant, but in extreme cases, it may involve a major disruption of the organization, requiring them to move or close down. One small, collectively-run, solar power firm was forced to move its headquarters several times through this sort of legal harassment. At one site, the local authorities charged over a hundred building "violations" (Etzkowitz, 1978). An even more far-reaching legal obstacle is the lack of a suitable statute for incorporating employee-owned and controlled firms. The Alternative Newspaper, for example, had to ask an attorney to put together corporate law in novel ways in order to ensure collective control over the paper.¹¹

The law can be changed but the more ubiquitous forces against collectivism are social, cultural, and economic. In fact, alternative organizations often find that bureaucratic practices are thrust on them by established institutions. The Free School, for example, began with an emphatic policy of absolutely no evaluative records of students. In time, however, it found that in order to help its students transfer back into the public schools or gain entrance into college, it had to begin keeping or inventing records. The preoccupation of other organizations with records and documents may thus force record keeping on a reluctant free school. In another free school, the presence of a steady stream of government communications and inspectors (health, building, etc.) pushed the

organization into creating a special job to handle correspondence and personal visits of officials (Lindenfeld, 1979).

Alternative organizations often strive to be economically self-sustaining, but without a federated network of other cooperative organizations to support them, they cannot. Often they must rely on established organizations for financial support. This acts as a constraint on the achievement of their collectivist principles. For instance, in order to provide free services, the Free Clinic needed and received financial backing from private foundations as well as from county revenue-sharing funds. This forced them to keep detailed records on expenditures and patient visits and to justify their activities in terms of outsiders' criteria of cost-effectiveness.

In less fortunate cases, fledgling democratic enterprises may not even get off the ground for failure to raise sufficient capital. Two recent attempts by employee groups to purchase and collectively manage their firms reveal the reluctance of banks to loan money to collectivist enterprises, even where these loans would be guaranteed by the government. From the point of view of private investors, collective ownership and management may appear, at best, an unproven method of organizing production, and at worst, a dangerous method.¹²

For a consistent source of capital, collectivist enterprises may need to develop cooperative credit unions as the Mondragón system has done (Johnson and Whyte, 1977) or an alternative investment fund. In many collectives, the unpaid (or poorly paid) labor of the founders forms the initial capital of the organization, enabling some measure of financial autonomy. In any case, the larger issue of organization-environment relations remains problematic, particularly when we are considering collectivist-democratized organizations in a capitalist-bureaucratic context.¹³

¹¹ The result of this effort was a two-tiered structure: the paper was incorporated as a general corporation and a trust, which owns all the stock in the paper. Each six months of full-time work is worth one voting share in the trust. This grants ultimate control of the paper to the staff, past and present. Immediate control is exercised by the board of directors of the corporation, which consists of the currently working staff. As a member of the paper said, "the structure is neither graceful nor simple, but it . . . guarantees that the working staff will maintain editorial control, and makes it nearly impossible ever to sell the paper."

¹² See, the abortive attempts to raise capital for employee-ownership at Kasanof's Bakery, *The Boston Phoenix*, April 26, 1977, and at the Colonial Press in Clinton, Massachusetts.

¹³ Organization-environment relations are always reciprocal. In part, the low wages, hard work and intense personal involvement that make collectivist

Individual differences. All organizations, democratic ones notwithstanding, contain persons with very different talents, skills, knowledge, and personality attributes. Bureaucracies try to capitalize on these individual differences, so that ideally people with a particular expertise or personality type will be given a job, rewards, and authority commensurate with it. In collectives such individual differences may constrain the organization's ability to realize its egalitarian ideals.

Inequalities in influence persist in the most egalitarian of organizations. In bureaucracies the existence of inequality is taken for granted, and in fact, the exercise of power is built into the opportunity structure of positions themselves (Karter, 1977). However, in collectivist organizations, this may be less true. Here, precisely because authority resides in the collectivity as a unit, the exercise of influence depends less on positional opportunities and more on the personal attributes of the individual. Not surprisingly, members who are more articulate, responsible, energetic, glamorous, fair, or committed carry more weight in the group.¹⁴ John Rice, a teacher and leader of Black Mountain (a group that "seceded" from the educational system and anticipated the free school movement) argued that Black Mountain came as close to democracy as possible: the economic status of the individual had nothing to do with community standing. But beyond that, "the differences show up . . . [;] the test is made all day and every day as to who is the person to listen to" (Duberman, 1972:37).

Some individual differences are accepted in the collectivist organization, but not all, particularly not differences in knowledge. In bureaucracy differences of skill and knowledge are honored. Spe-

cialized jobs accompany expertise. People are expected to protect their expertise. Indeed, this is a sign of professionalism, and it is well-known that the monopolization of knowledge is an effective instrument of power in organizations (Weber, 1968; Crozier, 1964). For this very reason, collectivist organizations make every attempt to eliminate differentials in knowledge. Expertise is considered not the sacred property of the individual, but an organizational resource. In collectives, individually-held skills and knowledge are demystified and redistributed through internal education, job rotation, task sharing, apprenticeships, or any plan they can devise toward this end.¹⁵

The diffusion or demystification of knowledge, while essential to help equalize patterns of influence, involves certain trade-offs. Allowing a new person to learn to do task X by rotating her/him to that job may be good for the development of that person, but it may displace an experienced person who had received a sense of satisfaction and accomplishment in job X. Further, encouraging novices to learn by doing may be an effective form of pedagogy, but it may detract from the quality of goods or services that the organization provides, at least (theoretically) until universal competence in the tasks of the organization is reached.

Even in the collectivist organization that might achieve universal competence, other sources of unequal influence would persist (e.g., commitment level, verbal fluency, social skills).¹⁶ The most a democratic organization can do is to remove the bureaucratic bases of authority: positional rank and expertise. The task of any collectivist-democratic workplace, and it is no easy task, is to eliminate all bases of individual power and authority, save those that individuals carry in their person.

organizations seem so costly may be due to costs imposed by the environment. Conversely, collectivist organizations rely upon goods and services produced by the surrounding bureaucratic organizations, e.g., light bulbs, fast food chains.

¹⁴ Swidler (1976) vividly describes the extent to which members of a free school will literally ransack their private lives to locate sources of glamour that will enhance their sense of worth and influence in the group.

¹⁵ A case study of the demystification of skills in a collectivist work organization is provided by Bart (1979).

¹⁶ Mansbridge (1977) observes that even the most genuinely democratic organization will accept some measure of inequality of influence in order to retain individual liberties.

Figure 1. Range of Organizational Forms

Conclusion

The organizations in this study are admittedly rare and extreme cases. To the extent that they reject received forms of organization, they present an anomaly. For precisely this reason they are of great theoretical significance. By approaching the polar opposites of bureaucracy, they allow us to establish the limits of organizational reality. The parameters appear to be far wider than students of organizations have generally imagined. Once the parameters of the organizational field have been defined, concrete cases can be put into broader perspective. Professional organizations, for example, while considerably more horizontal than the strictly hierarchical bureaucracy (Litwak, 1961), are still far more hierarchical than the collectivist-democratic organization. Thus, we may conceive of the range of organizational possibilities illustrated in Figure 1.

By contrasting collectivist democracy and rational bureaucracy along eight continuous dimensions, this paper has emphasized the quantitative differences between the two. In many ways, this understates the difference. At some point differences of degree produce differences of kind. Fundamentally, bureaucracy and collectivism are oriented to qualitatively different principles. Where bureaucracy is organized around the calculus of formal rationality, collectivist-democracy turns on the logic of substantive rationality.

If, in the Weberian tradition, we take the basis of authority as the central feature of any mode of organization, then organizations on the right half of Figure 1 empower the *individual* with authority (on the basis of office or expertise), while organizations on the left side grant ultimate authority only to the *collectivity* as a whole unit. Moreover, if, following

Marx's lead, we take the division of labor as the key to the social relations of production, organizations on the right side of the diagram maintain a sharp division between managers and workers, while organizations on the left side are integrative: those who work also manage. Departures of this magnitude from established modes of organization may be considered a "social invention" (Coleman, 1970).

Organization theory has for the most part considered only the right half of this spectrum, and indeed, the vast majority of organizations in our society do fall on the right side of the continuum. Still, we gain perspective on these organizations by putting them into a broader frame of reference. With the proliferation of collectivist organizations both in this society and in others (e.g., China, Spain, Yugoslavia), we will need an alternative model of organization, one which they themselves aspire toward, by which to assess their impact and success. To wit, collectivist organizations should be assessed not as failures to achieve bureaucratic standards they do not share, but as efforts to realize wholly different values. It is in the conceptualization of alternative forms of organization that organizational theory has been weakest, and it is here that the experimentation of collectives will broaden our understanding.

THE RELIGIOUS SWITCHER IN THE UNITED STATES*

FRANK NEWPORT

University of Missouri, St. Louis

American Sociological Review 1979, Vol. 44 (August):528-552

This paper examines trends, patterns and implications of religious mobility in the United States. Previously published data, and analysis of 1975-76 NORC data indicate that about 25% to 32% of American adults have switched religions (including movement out of religion) in their life times. High and Low Status denominations are gaining members due to switching (more in-mobility than out-mobility), and Baptists, Catholics and Medium Status denominations are losing members due to switching. The most common pattern of religious movement is out of religion altogether. Additional analyses show that religious switching patterns are congruent with explanations stressing the switcher's desire to worship with individuals of similar socioeconomic status, that some switching is the result of an individual moving to the religion of a stable spouse, and that movement out of religion is disproportionately composed of young people.

The American religious system evidences a remarkable degree of diversity of specific religious groups within an overall, broadly similar Christian framework. Eighty-five percent of all Americans report Christian affiliation, but with a dizzying array of well over 200 major, identifiable churches, denominations and sects (Jacquet, 1978:228).

Given this highly differentiated, yet generally similar set of religious bodies in the United States, it would seem reasonable that we would find a good deal of movement of individuals from religious body to religious body in an American process of religious mobility. These types of changes are made easy by the large number of potential sites for church memberships, and by the fact that the shift can usually be accomplished without the traumatic necessity of drastically altering one's basic beliefs, or rituals, or styles of religious interaction.

The study of this religious mobility

makes two specific contributions to the general attempt to understand religion in American society. First, it can be useful in analyzing general trends and patterns in religious affiliation, and in particular in understanding overall gains and losses in membership by religious bodies. Second, the analysis of religious mobility gives us an opportunity to understand the functions that religion plays in the lives of its adherents. If we identify those variables significantly related to religious switching, such as age, or socioeconomic status, or region of country, we can make reasonable inferences about the role that religion plays in the lives of these mobile individuals. These inferences, we assume, can lead us to more general conclusions about religion and its functions in contemporary American society.

Rodney Stark and Charles Glock (1968) initiated a recent renaissance of interest in religious switching with their inclusion of a chapter on the topic in *American Piety*. Since then a number of studies have appeared in the literature dealing with the amount and type of switching, and with explanations for the observed mobility. Of great significance has been the inclusion by the National Opinion Research Corporation of careful and detailed questions about respondents' religious affiliation, and the religious affiliation of the respondents' parents, in their annual General Social Surveys. The presence of these variables, and the general availability and usefulness of the Surveys, have created a

* Direct all communications to: Frank Newport; Department of Sociology/Anthropology/Social Work; University of Missouri, 8001 Natural Bridge Rd.; St. Louis, MO 63121.

This is a revised and expanded version of a paper presented at the annual meeting of the Southwestern Social Science Association, Dallas, 1977. The data utilized in this paper were made available by the Inter-University Consortium for Political and Social Research, and originally were collected by James A. Davis of the National Opinion Research Center, University of Chicago. Neither the original collector of the data nor the consortium bear any responsibility for the analyses or interpretations presented here.

situation in which religious mobility can now be studied in some detail, using a nationwide, reliable sample of individuals from the United States.

Using information in previous studies in the research literature, and the information gained from new analyses of the NORC data gathered in 1975 and 1976, this paper will investigate and summarize what we know about religious switching in this country. We will have two primary goals in presenting this material: first, to arrive at a relatively thorough description of the amount and process of mobility in the United States, and second, to examine empirical support for several of the more prominent theoretical explanations for the observed mobility. A fairly comprehensive picture of religious mobility in this country should emerge from these analyses, one which will give us a good sense of the implications of this mobility for the study of religious behavior in general.

Data. The analyses in this paper will be accomplished on a combined sample from the 1975-76 General Social Surveys of NORC, with an N of 2,689. These data, as evidenced by the wide use to which they have been put in recent years, are extremely useful to scholars of the sociology of religion. (Further technical information on these data is obtainable in ICPSR, 1975; 1976.)

Religion is coded by NORC into the following categories: Catholic, Protestant, Jewish, Other and No Religion; for Protestants, it is further coded into some 97 different Protestant categories. The combination of this information produces a nominal level religion variable with 101 levels, somewhat cumbersome for most analysis procedures. There are two ways of handling this variable. The first is to collapse into theologically similar categories (such as the "liberal denominations," "moderate denominations," and "conservative denominations" categories used by Stark and Glock). The second is to collapse into categories containing denominations similar on other variables, the most useful of which is the socioeconomic status of members. In point of fact, both of these procedures yield categories which contain roughly the

same denominations, with high socioeconomic status denominations being the ones included in the liberal category. For the present analyses, I created socioeconomically homogeneous categories of religion as follows: (1) High Status denominations (Episcopalians, Presbyterians, Congregationalists, and others), (2) Medium Status denominations (Methodist, Lutheran, and others), (3) Baptists,¹ (4) Low Status denominations (Christian, Jehovah's Witnesses, Pentacostal, Assembly of God, and others), (5) Protestant, but no denomination, (6) Catholic, (7) Other, (8) Jewish, and (9) No Religion.²

The respondents in the NORC surveys were approximately half male and half female. At various points in the analyses which follow, we will use the basic sample, Heads of Households (males, single and divorced females, and spouses for married females), and males and single females only. These will be noted at appropriate points.

DESCRIPTION OF RELIGIOUS MOBILITY

Amount of Religious Switching

Although the primary purpose of this paper is not to investigate trends in religious mobility over time, we can look briefly at summary statistics reported in the literature which deal with data collected as long ago as 1955. The study of trends in mobility is a rather complex problem, as has been well documented (Duncan, 1966), and such analyses usually require as a starting point a basic mobility transition matrix, which is not provided in several of the studies under review here. All of the studies, however, do report basic information on the percent of those interviewed who are in a different religion at the time of the survey from the one in which they report being raised. This basic statistic, *percent mobile*, is reported for seven studies, and for two different analyses of the 1975-76 data, in Table 1. We should be careful to emphasize here

¹ A separate category was created for Baptists, since they constitute the largest Protestant denomination in the United States.

² At some points in the analysis, a more detailed 13-category scheme will be used.

Table 1. Percent Mobile, Eight Studies of Religious Mobility

Reported in	Data Collected	Sample	% Mobile	# of Categories
Alston (1971)	1955	National M/F	15.5%	11
Warren (1970)	1960	National Males Only	17%	²
Nelson and Snizek (1976)	1960	National M/F	24%	10 ³
Lauer (1975)	¹	Midwestern Com- munity of 11,000 Heads of Household	24%	12
Stark and Glock (1968)	1965	National M/F (Whites Only)	35%	11
Marty et al. (1968)	1965	National M/F	20%	10
Roof and Hadaway (1977)	1973- 1976	National M/F	25.84%	8 ⁴
(Present Analysis)	1975- 1976	National Heads of Household	30%	13
(Present Analysis)	1975- 1976	National Heads of Household	28.12%	9

¹ No date indicated.² Not indicated.³ Excludes none.⁴ Excludes none and Jewish.

that this figure is affected by the degree of inclusiveness of the categories used in coding the data (information provided in the far right-hand column of Table 1). Note that the percent mobile in the 1975-76 data rises from 28.12% to 30% when we change from a 9-category to a 13-category coding scheme.

The 25.84% figure from Roof and Hadaway's (1977:410) data is a weighted average calculated from their broad sub-categories as reported in their Table 1. (The figure for Protestants only for these data is 31.75%.) Their categories of religious origin exclude Disciples of Christ, no religion, and various small Protestant bodies. In addition, Roof and Hadaway do not indicate what categories of destination religion were used in the basic calculations of their mobility rate.

Alston's (1971) figure of 15.5% in 1955 and Warren's (1970) report of 17% mobile in 1960 are the two outliers among these figures. Warren's figure is particularly noteworthy, since it is a full 7% less than the figure of Nelson and Snizek (1976), even though both data sets were collected in the same year (1960) from nationwide samples. Warren's sample deals with men only, which may account for some of the

difference.³ A more probable explanation for the differences may be the coding scheme used, since Warren apparently utilizes a very broad scheme of only three major Protestant groupings, which could account for the relatively low percent mobile rate he reports. There is no ready explanation for Alston's low figure, other than the most obvious: there was, in the United States, less switching in the 1950s than in more recent years.

Processes of Religious Switching

We turn now to the important question of the dynamics or precise patterns which constitute the reported religious switching behavior. In particular, we are interested in three areas: (a) the percent of individuals leaving the various religious bodies, (b) the percent of individuals moving into the various religious bodies, and (c) the specific paths of mobility from particular religious body to particular religious body.

Only three of the studies in Table 1 report data which can be used to address

³ Analyses of the 1975-76 data, however, indicate a very small difference between men and women in the percent mobile.

these problem areas: Stark and Glock's (1968) important analysis of the switching process using data collected in 1965, Lauer's (1975) report of data gathered in a "small midwestern community" (for which no date is given), and, to a limited degree, Roof and Hadaway's (1977) analysis of national data collected in the mid-1970s. After a brief review of these three reports, the 1975-76 data will be analyzed in detail.

The data used by Stark and Glock (1968:191-4),⁴ as they are careful to point out, have limitations, but their analyses are seminal and mark the benchmark against which all subsequent analyses must be compared.

Stark and Glock reach seven basic conclusions from their analyses. First, liberal denominational bodies were gaining in membership, while conservative bodies were losing membership when the net gains or losses due to switching were calculated. Second, this process seemed to be taking place because of a movement from the conservative Protestant bodies into the liberal Protestant bodies:

Thus these national data provide a cautious confirmation of the trends revealed in the California data: in the process of Protestant church-switching liberal and moderate bodies are gaining membership at the expense of conservatives. (1968:198)

Third, there was a slight tendency for this pattern of movement to be accentuated in urban as opposed to rural areas (1968:199-200). Fourth, the liberal denominations actually held on to *fewer* of their members than did the Baptists and Catholics, but they managed to attract many more in-migrants. This explains the gain due to switching by the liberal denominations, and the loss due to switching by the Baptists (and the stability of Catholics). Fifth, there was a considerable net loss due to switching experienced by the *No Religion* category (-31%). Sixth, Stark and Glock speculated about the existence of an "up and out" effect

wherein the low and moderate denominations' members moved up into the liberal denominations, with the members of the liberal denominations moving out of active participation in religion altogether. Finally, Stark and Glock (1968:199, 203) discussed the difference between changes in membership figures recorded by the denominations, and the net gains and losses due to switching calculated from their data. Most of these findings will be discussed in some detail in conjunction with the analysis of the 1975-76 data below.

Lauer's (1977:384) data are reported in a simple cross-tabulation table which evidences the same basic trends observed in Stark and Glock's nationwide sample. The liberal denominations (Episcopalian, Presbyterian, and Unitarian) enjoyed net gains in Lauer's midwestern community. Catholics and Baptists suffered net losses. Importantly, Lauer's data show a large *increase* in the number of individuals reporting no religion (30%), a significant and direct contrast to the findings of Stark and Glock.

Roof and Hadaway's (1977) analysis of the NORC General Social Surveys of 1973, 1974, 1975, and 1976 unfortunately is reported in a limited fashion. They do not present a full matrix or mobility table, they do not separate out the various destination categories of groups of religious switchers, they do not present data on the percent of the current numbers of adherents in a religion who were not raised in that religion (although these figures can be calculated from their presentation), and they exclude several categories of religion from their list of religions of origin.⁵

⁵ There are other problems. In Roof and Hadaway's Table 1, the percent "stayer" is reported for the broad category of *Protestant* as well as for the three subgroups of Protestant—Liberal Protestant, Moderate Protestant and Conservative Protestant—and for the distinct denominations which comprise these three subgroups. The number of individuals raised in the three subgroups in the table totals 2,952 compared with the total Protestant N of 3,330. The authors explain this difference by pointing out that they dumped several minor Protestant denominational members (presumably 378) into the total Protestant category. The three subgroups have percent stayer figures of 64.21%, 68%, and 74.3%, respec-

⁴ We will be dealing with Stark and Glock's nationwide data. They also look at switching among the respondents to a survey administered to church members in northern California.

Table 2. Mobility Matrix, Heads of Households 1975-76 NORC Data (%=% from Each Religion of Origin Category in Each Religion of Destination Category)

Religion at Age 16	Current Religion									
	High SES	Medium SES	Baptist	Low SES	Prot., No Denom.	Catholic	Jewish	Other	None

The data they do report provide confirmation of the basic trends of Stark and Glock. Their Table 1 (1977:410) indicates net losses for Baptists and Catholics due to their inability to attract new members, and net gains for Episcopalians and Congregationalists due to their recruitment of new members, despite the fact that these latter, liberal denominations experience relatively heavy out-migration. (In addition to these basic data on switching, Roof and Hadaway analyze the relationship among the sex, age, and region of respondents and switching rates. Some of these data will be discussed in a later section of this paper.)

The results of the present analyses of the 1975 and 1976 NORC General Social Surveys are contained in Tables 2, 3, 4, and 5.

Table 2 presents the basic mobility matrix for the 1975-76 data, showing the out-flow percentages of individuals from the nine categories of religious origin into each category of religious destination.

Table 3 presents a summary of the mobility patterns of the nine religious

categories, including the percentage composition of each category who are lifelong members, and the percentage composition of the categories who are new converts or in-migrants.

Table 4 presents data on the expected vs. observed frequencies in the cells of the mobility table, calculated on the assumption of quasi-independence as developed by Goodman (1969a; 1969b) and others, and as applied in the mobility analyses of Blau and Duncan (1967), Featherman et al. (1973), and others. The assumption of quasi-mobility allows us to calculate expected values free from the distorting influence of the numbers of respondents in the diagonal or nonmobile cells. It has been shown (Goodman, 1969a) that the more usual calculation of expected frequencies under a basic assumption of simple independence (following the formula

$$E = \frac{m_i m_j}{n}$$

where m_i and m_j are the marginal frequencies associated with row i and column j), results in expected values which mirror diagonal values and distort interpretations of comparisons of these expected values with obtained or observed frequencies in the usual "mobility ratios." The assumption of quasi-mobility is that, ignoring those individuals who are not mobile (that is, those in the diagonal cells), the probabilities associated with destinations of the mobile individuals should be a simple combination of the probability effects of the rows and columns of origins and destinations. The pro-

tively. Yet the percent stayer for the total Protestant column (89% of which is the three subgroups) is 89.6%. Either the total Protestant figure, or the subgroup figures are evidently in error. Additionally, it would seem that the denominations into which the three Protestant subgroups are broken down would be exhaustive, as would be indicated by the fact that the denomination numbers in the column Religion in Which Raised do add up to the subgroup totals. But the numbers in the joiners and leavers columns do not add up to the totals for these columns for the subgroups.

Table 3. Indicators of Religious Stability and Mobility, Heads of Household, 1975-76 NORC Data

	Religion in Which Raised	Current Religion	Net Gain or Loss Due to Switchers	% Raised in Religion, Currently in Religion	% Current Religion Not Raised in Religion
High SES	239	248	+ 3.8%	66%	37%
Medium SES	694	602	- 13. %	67%	23%
Baptist	622	550	- 11.6%	75%	15%
Low SES	150	167	+ 11.3%	55%	50%
Prot., No Denom.	56	114	+104. %	57%	72%
Catholic	758	679	- 10.4%	82%	8%
Jewish	55	48	- 13. %	82%	6%
Other	20	29	+ 45. %	75%	48%
None	95	252	+165. %	47%	82%

cedure, in other words, uses only mobile individuals in the calculation of expected values. The ratios which result from the division of the observed frequencies to these expected frequencies tell us if respondents are over- or underrepresented in a destination category, based on a standard of independent distribution of the respondents from a particular origin category among the destination categories. The actual calculation of the expected frequencies in each nondiagonal cell followed the procedures outlined by Goodman (1969b: 847-9). The expected values, observed values, and "quasi-mobility ratios" are displayed in Table 4.

Table 5 presents the index of status persistence (Goodman, 1969b). This index is based on the assumptions of quasi-independence discussed above. It assumes that the same proportion of individuals from religion of origin j should flow into destination category j as would be predicted for individuals flowing into that destination category from any of the other (non- j) religions of origin. The actual formula for the index, as given by Goodman, is $\hat{G} = (\hat{A}_j - \hat{R}_j) / (1 - \hat{R}_j)$, where \hat{A}_j is

the observed proportion of individuals from j who flow into destination j , and where \hat{R}_j is the proportion of all nonstable individuals expected to flow into j , under the assumption of quasi-independence (Goodman, 1969b: 838). The numerator of the index subtracts the observed percentage in destination category j from origin category j , from the expected percentage in destination category j . The index then divides this number by the percentage of individuals *not* expected to flow into destination category j . Thus, the index reports the degree to which individuals flow into the same destination category as origin category, above and beyond the percentage expected, based on the assumption of quasi-independence.

It is apparent from Table 3 that the same basic trends identified by Stark and Glock appear in the 1975-76 data. Catholics, Baptists, and the Medium Status Protestant denominations are losing membership overall due to switching (that is, fewer respondents indicated a current affiliation with these groups than indicated that they had been raised in these religious groups). High Status Protestant denomination,

Baptist	.718
Low SES	.498
Prot., No Denom.	.523
Catholic	.805
None	.299

Low Status Protestant denominations, the two areligious categories, and the *Other* category are gaining membership due to switching.

Again in these data, the Baptists and Catholics retain a high percentage of their membership. As can be seen, 75% of those interviewed who indicated having been raised in the Baptist faith were still Baptist, and 82% of those who reported having been raised Catholic were still Catholic at the time of the survey. These statistics are supported by the Goodman indices of status persistence, summarized in Table 5 (Baptist = .718, Catholic = .81). The index values show that Baptist and Catholics are very likely to keep their religion of origin, when compared with the rate at which non-Catholics and non-Baptists move into the two faiths.

Baptists and Catholics are not successful at attracting new members. About 15% of respondents who are currently Baptist come from another faith, and only 8.4% of respondents who are currently Catholic were not raised Catholic. Thus, the reason for the observed overall losses due to in-and out-mobility of these two faiths is that they apparently cannot attract sufficient numbers of new members to offset their losses.

The Medium Status religions have a similar pattern of in- and out-mobility. They retain fewer of their members (67%) and their current membership is composed of a greater percentage in-mobiles than the Baptist or Catholic faiths, but overall, as can be seen, the Medium Status religions have a net loss due to switching quite close to that of the Baptist and Catholics (-13%). The particular combination of heavy loss and some immigration from other religious groups yields a fairly low index of status persistence,

.567, which indicates that about 57% of expected movement of Methodists to other religions in fact is composed of stability within the Methodist religion.

The High and Low Status religious categories evidence a pattern of movement in which they lose a considerable percentage of their original membership, yet show a net gain due to switching because of their success at attracting new members. Note that about 37% of current High Status religions' affiliates came from other religions, and that fully 50% of those who indicate a current identification with the Low Status religions came from other religions of origin. As would be predicted, the indices of status persistence are relatively low for these two groups, .61 and .498, respectively.

It is the *No Religion* category which has the most spectacular growth pattern due to switching. Eighty-two percent of those who indicate no religious preference were raised in one of the other religious categories, and overall, 27.3% of all respondents who switched moved into the No Religion category (38.2% if we include those who switched into *Protestant, No Denomination*). This is the modal switching pattern evidenced in these data.

Table 4 gives us further insights into the relationships evidenced in the data. Note that, as would be expected, there is less movement from the Protestant denominations into the Catholic faith, and less movement into the Protestant denominations from the Catholic faith than we would expect under our assumptions. Importantly, note that the movement of those individuals raised Catholic into the No Religion category is much higher than expected (ratio = 1.95), a movement which in fact constitutes the highest mobility ratio in the entire mobility table. Catholics, in other words, are relatively stable except in their movement out of religion altogether.

The Low Status religions receive their new members disproportionately from the Baptists and Medium Status religious groups. It is interesting to note that the individuals raised in the High Status religious group move into the Medium Status group, but have less movement than ex-

pected into the Low and Baptist religious groupings (the low N's involved here make these ratios tentative).

Generally speaking, Table 4 is remarkable because of the lack of departure from the quasi-independence assumptions (i.e., ratios near unity), rather than for any demonstrable patterns of relationship in the choosing of one's destination religion. What this means, of course, is that those individuals who switch religions appear to distribute themselves among all of the possible destination religious categories in a fairly similar fashion, regardless of category of origin.

There are three additional patterns evidenced in these tables which warrant further discussion.

(1) Stark and Glock (1968:203) discussed the possibility that their data indicated an "up and out" trend in religious switching wherein lower status Protestants moved to higher status denominations, and High Status denominational members moved out of religion altogether. It is apparent from Table 4 that Protestants are overrepresented in movement to denominations of higher status, as can be seen by the generally positive ratios to the left of the diagonal for the second, third, and fourth rows. And, as can be seen, the High Status denominational members do not drop down to the Low Status and Baptist religions, and they move at a slightly higher than expected rate into the No Religion category. But, it is not a perfect picture of up and out mobility. Note that High Status members move into the Medium Status denominations, and that Medium Status denominational members and Baptists move into those denominations lower on the status scale.

(2) What accounts for the remarkable increase in measures of flow into the No Religion category, when we compare the 1975-76 data to those of Stark and Glock? There are a couple of possible explanations. It might be argued that the differences are a result of an increased willingness on the part of respondents to state publicly that they are not a member of a religious group. Thus, the 1970s might have ushered in an era in "truth in reporting" in religion, rather than an in-

creasingly secular era. This explanation, however, is at least partially countered by Wuthrow's (1976:858) compilation of various indicators (not just self-reports) of secularization, all of which show a decrease in religiosity in recent years. If the No Religion category's increase reflected only a change in reporting style, then we would expect little change in other indicators such as building expenses and contributions. Wuthrow's data contradict this.

So we may be left with the most obvious explanation for the measured increase in flow into the No Religion category: that it is a valid reflection of a general secularizing trend in our society. One theory of secularization, that of the demographic transition in age composition of the religious groups, will be discussed in some detail in a following section of this paper.

(3) Some researchers have attempted to deal with the difference between the gains and losses due to switching evidenced in religious mobility data and changes in membership figures over the years as reported by the various religious bodies. Stark and Glock (1968) spend a good deal of time discussing this apparent contradiction:

First of all, membership figures reported annually to the National Council of Churches have long shown that the conservative churches are growing faster than the moderate and liberal bodies. But our data suggest that the conservative bodies ought to account for a smaller proportion of church members each year. (1968:199)

But there is another apparent puzzle revealed by our findings. The trend to liberalism ought to be causing a considerable expansion in the size of the liberal and moderate denominations in terms of enrolled members at the congregation level. But this seems not to be happening. These bodies have not reported substantial increases in membership. (1968:203)

Stark and Glock discuss several possible explanations for these facts, centering around the unreliability of church membership statistics, the important difference between the denominational affiliation an individual states to a survey interviewer and a person's actual church membership,

and differentials in church membership (not affiliation) by denominations.

The membership patterns for the various religious groups in recent years are fairly clear. The Episcopalian Church, for example, has decreased from a membership figure of 3,429,153 in 1965 to a membership of 2,882,064 in 1976. The Southern Baptist denomination, on the other hand, has increased in membership over the same 11-year period from 10,770,573 to 12,917,992. Similarly, the Roman Catholic church has increased in membership from about 46 million to 49 million in 1976. (All of these figures are from Jacquet, 1978: 230-1.)

But this contradiction between the gains and losses due to switching, and gross membership changes in the religious categories need not be puzzling. There does not have to be a direct positive relationship between mobility into and out of various religious categories and the general rates of increase and decrease in these categories over time, because growth in a population unit in a time interval is due to several demographic processes, including both mobility and natural fertility and mortality trends.⁶ The data on gains and losses due to switching serve as an estimate of the difference between in-migration and out-migration for the population unit (i.e., the religious categories). Stark and Glock, in their 1968 chapter, look at the differences between this migration difference for the religious bodies and the overall growth figures, and attempt to find explanations for the fact that they were not correlated. The obvious reason for the differences, as we have been suggesting here, is that births and deaths are different for the various religious categories, and that these differential fertility and mortality rates (which Stark and Glock do not consider) account for a greater share of the variance of growth in the interval than do the migration differences.

There are some data to support this line of reasoning. Table 6 presents data on the average age of the nine religious

categories. As can be seen, the average age for Baptists, Low Status denominations, and Catholics is lower than the average for the other Protestant denominations. This age structure suggests the high fertility hypothesis has some validity, since low average age in an adult population indicates large numbers of individuals in child-bearing years and large cohorts of young people recently moved into adult ranks.⁷ Additionally, Baptists and Catholics retain a higher percent of their membership than do the other Protestant denominations. Thus, it may be that Baptists and Catholics have more children and retain a greater percent of these children than do the High and Medium Status denominations, and thus, the Baptists and Catholics show absolute increases in membership year in and year out, even though they are losing members overall due to switching. And, similarly, the High Status denominations, even though gaining slightly due to switching, experience gross losses in membership over time because of their high mortality and lack of fertility.

Finally, we should not lose sight of the fact that the gains and losses due to switching reflected in our data are processes potentially extending over a time span of about 75 years. Thus, it is very hazardous to compare these mobility figures with changes in membership estimates taken at precise points in time, because we have no accurate fix on the time periods involved in our reported mobility. As Duncan (1966) points out, retrospective indicators of Father's occupation and other characteristics (such as religion at age 16) cannot be used to construct estimates of specific previous cohorts or generations on these characteristics.

Summary

Several facts have been made clear by our examination of data on religious switching:

⁷ Other analyses show that Baptists, Catholics, and Low Status denominations report more children in the home at the time of the survey than the other groups. This could also support the idea that these groups grow because of internal production of new members.

⁶ As Matras (1977:113) indicates: "Growth in time interval = births in interval - deaths in interval + # of in-migrants - # of out-migrants."

Catholic	43.8 (10)	48.58 (26)	44.08 (12)	42.56 (16)	37.0 (7)	42.88 (661)	37.0 (2)	29.5 (2)	33.81 (68)
Jewish		66.0 (1)	51.0 (1)	32.0 (1)		23.0 (1)	51.46 (96)		40.71 (7)
Other	46.0 (2)	38.0 (1)	28.0 (1)			43.67 (6)		36.0 (15)	61.00 (3)
None	37.88 (8)	43.53 (19)	36.0 (12)	37.29 (7)	43.5 (4)	60.83 (6)		22.0 (2)	30.15 (33)
	48.34	48.61	44.54	44.59	46.09	43.24	50.31	31.86	34.52

1. Only about 25 to 32% of the American population report current membership in a religious group (including areligious categories) other than the one in which they were raised.
2. The religious category which enjoys the greatest in-migration is the No Religion category. Fully 27.3% of all switching is composed of movement into this category, despite the fact that only 3.5% of the population report being raised in the category. Thirty-four percent of this movement into the no religion category is from the Catholic faith, by far the largest contributor, both in terms of raw numbers and in terms of expected values.
3. There is, as would be expected, less switching from Protestant to Catholic and from Catholic to Protestant religious groupings than would be expected under certain assumptions of an independent distribution of out-migrants from the various religious categories.
4. Baptist and Catholics retain high percentages of their members, but lose overall due to switching because they cannot attract significant numbers of new members.
5. The High and Low Status Protestant denominations lose much higher percentages of their membership, yet they gain overall due to switching because they have been very successful in attracting new members.
6. The midrange Protestant denominations lose members, and fail to attract enough new members to compensate for this out-migration.
7. The distinction between year-by-year changes in total membership of the religious categories, and the gains and losses due to switching must be emphasized. The relative losses and gains due to switching discussed in these pages do not necessarily imply an overall increase or decrease in the gross membership figures, because such membership changes can be due in large part to fertility and mortality trends.

EXPLANATION OF RELIGIOUS SWITCHING

Introduction

We can now turn to an examination of the *reasons* for the observed religious switching behavior, and ultimately to an investigation of what these reasons can tell us about the general functions of religion in our society.

It is useful here to distinguish between two types of functions of religion: the individual, personal, spiritual function and the organizational or social function.

Emphasis on the individual functions of religion suggests that the religious switch takes place because the individual seeks a new, different, or more personally meaningful theology, pattern of ritual, or style of ministry. (This type of explanation appeals to theologians and ministers who presumably like to assume a religiously rational, concerned and committed religious constituency.) The social or organizational emphasis assumes that religious affiliation implies association with a membership of a particular composition in a specific location and that the switch occurs because the individual desires to worship with or associate with certain types of people or in a specific location.⁸

The importance of these two emphases may vary for different categories of the mobile population. In particular, it may be that the social functions of the destination congregations or membership may be most important to the religiously upwardly mobile, and that the personalistic functions may be most important to the religiously downwardly mobile. This type of explanation is suggested by the work of Stark (1972), whose analyses support the idea that individuals at different socioeconomic levels use religion for different reasons.

We will look in this section primarily at

⁸ There are no doubt switches of "convenience" (e.g., on moving to a small town, the individual could find there is no Episcopalian church, and therefore moves to a Methodist affiliation), and switches due to religiously exogamous marriages. This latter explanation, which we will look at briefly in subsequent sections of this paper, involves some combination of other explanations for religious switching as the couple reaches a decision about affiliation with the two religions they bring to the marriage dyad.

social and organizational explanations for the religious switch.⁹ We have little data available on personalistic explanations (see Marty et al., 1968, for some limited responses to direct personalistic questions about the reasons for religious mobility) and the validity of such data, even if available, would be problematic.¹⁰

Socioeconomic Reasons for Religious Mobility

Introduction. The idea that socioeconomic status "causes" religious affiliation or behavior is related to two lines of thought in the sociology of religion. The classic discussions of the origins of denominations and sects (Niebuhr, 1929; Fallding, 1974) stress the fact that religious bodies develop to serve the needs of certain socioeconomically distinct groups in society. The second line of thought stresses the idea that *within* an already existing framework of denominations and religions, individuals might pick and choose a particular religious affiliation to go along with their education, occupation, or income. Within a Protestant framework of diverse but not radically distinct denominations in the United States, such a choice of "compatibility" in religious fellow worshippers can be accomplished without severe challenge to one's basic beliefs and upbringing.

The reasons for this need for status congruence between one's socioeconomic status and one's religious affiliation are straightforward. There are strong desires to associate with one's status peers as well as to accumulate the memberships, possessions and behaviors befitting one's socioeconomic station in life, presumably because of general principles of similarity and attraction and because of the need to certify to the public (as with clothes, cars, housing) one's attainments. Religious affiliation, we assume, can serve like other external status symbols as evidence of

one's socioeconomic position. Additionally, religious membership can be important for business and professional reasons, and for social contacts which can lead to other, non-religious, activities, associations and social networks of personal importance.

The actual theological *content* of denominations may vary in a manner which makes them more or less useful to groups of people at certain socioeconomic levels. Thus, the desire to shift to a religious affiliation with a compatible socioeconomic membership might reflect not only basic processes of status strivings, but also a desire to enjoy theology and preaching which, in Peter Berger's (1969) terms, "legitimate" or provide a "nomos" supportive of one's lifestyle, income, wealth, and outlook on life.

Past studies. Warren (1970) presented one of the first, although brief, analyses of the possible relationship between socioeconomic status and religious mobility. His data give some support to the hypothesis that individuals who switch religions may do so because of a desire to find a religious home more socioeconomically compatible than the religion in which they were raised. Warren's data and discussion, although dated, remain the best evidence available on the hypotheses under investigation, and as such stand as the baseline point for the current investigation.

Alston (1971) analyzes data obtained from a 1955 Gallup Poll. His main findings are that there are no significant differences between the average educational and occupational attainments of the groups of religiously nonmobile and mobile respondents. These results say nothing about the *social mobility* of his respondents, yet Alston states:

There are no statistically significant differences between the mobiles and non-mobiles in terms of education, occupation and age. This suggests that mobility is not associated with social mobility, since the two samples have similar educational and occupational profiles. (1971: 143-4)

In summary, religious mobility in 1955 was associated with only a limited amount of social mobility. . . . (1971: 148)

⁹ We will briefly look at age as a factor in the switch, and age can be considered to be related to some varieties of personalistic explanation.

¹⁰ Nisbett and Wilson (1977) argue that *any* self-report on the reasons for one's behavior is of doubtful accuracy.

This conclusion cannot be sustained by Alston's data, which as noted, deal only with *current* educational and occupational levels. There are a variety of ways in which there could have been actual differences in occupational mobility between the two categories of religious mobility as classified by Alston, yet which would not be evident in the data as presented.

Even if Alston's conclusions about the social *mobility* of his respondents are discounted, we need to examine the potential significance of his data as presented for other hypotheses concerning religious mobility and socioeconomic status (not mobility). Alston's presentations allow us to examine the relationship between switching per se or the lack thereof, and socioeconomic variables. If this switching per se is seen as the dependent variable (that is, as a result of occupational and educational status levels, not occupational mobility), then its theoretical relevance is unspecified. The only reasonable hypothesis along these lines would be that certain levels of social status lead to a general anxiety or desire to switch a variety of things, and that religious change might be one of them. Alston makes no mention of such a hypothesis, and its general relevance to the present concerns is doubtful. If religious switching per se is seen as the independent variable (that is, the cause of socioeconomic attainments), then we encounter methodological problems, since it has been well established that the effects of mobility as an independent variable are difficult to determine unless one has information on both the status of origin and the status of destination of the individuals involved (Duncan, 1966; Hodges, 1970; Hawkes, 1972). It first must be assumed that the apparent effects of mobility may be the simple result of the mobile individuals' statuses of origin and destination; and these assumptions must be discounted before the researcher can begin to analyze the presumed effect of mobility per se. Alston's data, again, allow for no such investigations.

Lauer (1975) makes similar logical errors in his analysis of data obtained from a telephone survey in a small midwestern community. All of his analytical procedures deal with categories of occupation-

ally mobile and nonmobile individuals, not with their statuses of origin or destination, about which no information is provided. Lauer (1975:387) reports finding no significant relationship between occupational mobility and religious mobility, and a weak relationship between *degree* of occupational mobility (within the group of occupationally mobile individuals) and religious mobility:

While no relationship exists between occupational and religious mobility per se, a high degree of occupational mobility increases the likelihood and possibly the pattern of religious mobility.

But, again, the interpretation of these relationships between categories of occupationally mobile and nonmobile individuals and religious mobility is difficult. The demonstrated relationships can be due to a variety of combinations of effects of average positioning on origin and destination occupational statuses, plus the possible effects of mobility per se. One cannot assume that they are due to mobility alone. Lauer concludes, for example, that individuals occupationally mobile across 5-9 categories are more likely to be religiously mobile than individuals occupationally mobile across 1-4 categories (see Lauer's Table 3). It is not too unreasonable to suggest that all of the respondents in the 5-9 category mobility group may have originated in either extremely high socioeconomic status categories or extremely low occupational status categories (depending on whether the mobility was up or down). And, it may be that starting life in one of these two extreme categories, *regardless of the extent of later occupational mobility*, may cause one to be religiously mobile, and starting life in one of the other less extreme categories, *regardless of the extent of later occupational mobility*, may cause one to be less religiously mobile. Thus, the statuses of origin alone of these occupationally mobile individuals well might have been the cause of the significant differences in religious mobility, a pattern of relationships which would make Lauer's (1975:387) conclusion that "... a high degree of occupational mobility increases the likelihood and possibly the patterns of religious mobility" incorrect.

Nelson and Snizek (1976) hypothesize that the basic relationship between occupational and religious mobility will vary by the urban-rural residence of the respondent. The authors use data obtained in a 1960 Presidential Election Survey, presented in a manner which crudely differentiates the *type* or form of occupational mobility or stability (i.e., white-collar stable, blue-collar stable, white-collar mobile and so forth). Their data suggest that there is a relationship between occupational mobility and religious mobility, and that this relationship is different for urban and rural categories of respondents, but Nelson and Snizek's analyses do not allow us to make very conclusive assumptions about these relationships. Their data need to be reanalyzed in a fashion which allows for differentiation to be made between category of occupation of origin and category of occupation of destination.

Analyses of the 1975-76 data. One test of the possible socioeconomic basis for religious switching is the comparison of the current socioeconomic status (SES) of religious switchers with the levels of stable members of both the origin and destination religions of these switchers (see Warren, 1970:145-9). If switching is independent of socioeconomic status,

switchers should be socioeconomically similar to others raised in their religion of origin. But, if individuals who switch religions do so in order to find socioeconomic compatibility between their SES and the SES of their destination religion, then we would predict a degree of correspondence between the switchers' own SES and average SES of the members of their destination religion, and differences between the switcher's SES and the SES of their religion of origin.

These assumptions can be tested by examining Tables 7, 8, and 9. Each table lists the average income, occupational prestige, or education for the group of individuals who have each possible combination of religion of origin and religion of destination. The underlined figures on the diagonal represent the averages of the three SES indicators for the religiously stable individuals, and serve as the primary benchmark for comparison in utilizing the tables.¹¹

¹¹ It should be noted that in the 1975-76 data set, there are no data on the precise point in the individual's career at which he or she switched religions. Thus, even a strong relationship between current socioeconomic status and the status level of destination religion members does not *necessarily* indicate that the switch itself was made for socioeconomic reasons. In particular, if the switcher chose the destination religion at a very early age, it might be re-

¹ Hodge-Siegel-Rossi Occupational Prestige scores. See ICPSR 1975; 1976.

The best way to examine each table is by looking across the rows. Baptists still in the Baptist religion at the time of the survey (stable Baptists), for example, have an average income of \$11,585. It can be seen that the individuals raised Baptist who have moved into high status denominations have an average income of \$19,184. And finally, note that the average income of the stable high SES religious group members is \$18,429. Thus, the switchers out of the Baptist denomination into the High Status denomination have average income levels much closer to the average income of the destination religion members than to the average income of the religion which they abandoned.

As can be seen, the same types of

trends are evident for all three of the socioeconomic status indicators. Switchers into the High Status Protestant denominations have consistently higher SES averages than the stable members of their origin religions.

If people are moving into the fundamentalist and Low Status religions (including perhaps the Baptist denomination) for reasons other than socioeconomic compatibility, then we would expect to find their average SES closer to the members of their religion of origin, than to the members of their religion of destination. But this is apparently not the case. The switchers who moved out of the High, Medium and Baptist denominations into the Low Status denominations have SES values much closer to the average SES of the Low Status denomination than their religions of origin. Thus, these figures are compatible with the hypothesis that switchers to Low Status denominations move in order to seek SES compatibility.

Note that those individuals who move to the No Religion category do not have particularly unusual status characteristics when compared with their religion of origin. This suggests that there are factors other than socioeconomic status which account for the decision to move to the No Religion self-placement.

sponsible for, rather than as a result of, later socioeconomic achievement. However, even such an early switch may have been a result of a form of "anticipatory socialization" into a desired or planned socioeconomic status, and thus would be congruent with the general notion of the compatibility between socioeconomic levels and one's religion. The major exception may be those instances where an individual switches purely because of the religion of his or her spouse, and later, due either to the spouse or to the religion, achieves socioeconomically at a level similar to those of the members of the destination religion. The influence of the spouse on religious switching will be investigated in a later section of this paper.

Table 9. \bar{X} Education for Each Category of Religion of Origin by Religion of Destination, Heads of Household, 1975-76 NORC Data

Religion at Age 16	Current Religion								
	High SES	Medium SES	Baptist	Low SES	Prot., No Denom.	Catholic	Jewish	Other	None

Baptist	13.6 (20)	11.9 (44)	10.55 (465)	7.5 (17)	12.3 (19)	12.3 (12)		11.5 (2)	12.03 (38)
Low SES	13.1 (10)	11.5 (18)	9.5 (13)	10.98 (83)	12.3 (11)	11.0 (6)			12.9 (9)
Prot., No Denom.	12.8 (5)	11.0 (4)	15.0 (2)	10.5 (2)	11.84 (32)	9.5 (2)		12.0 (1)	12.155 (8)
Catholic	13.0 (12)	11.6 (26)	10.9 (10)	9.1 (10)	13.6 (5)	11.97 (620)	13.0 (1)	16.0 (2)	13.5 (70)
Jewish	17.0 (1)	8.0 (1)		17.0 (1)		8.0 (1)	14.02 (44)		15.3 (6)
Other						14.0 (3)		14.4 (15)	10.5 (2)
None	13.8 (6)	12.6 (19)	11.9 (9)	9.7 (6)	10.75 (4)	12.2 (5)		16.0 (1)	11.56 (45)

The interpretation of these tables can be facilitated if we can create an index¹² which reflects the position of each switcher's status relative to the status of the members of his or her religion of origin, and relative to the status of the members of the religion of destination:

$$\text{INDEX VALUE} = \left[\begin{array}{l} \text{SWITCHER'S STATUS LEVEL} \\ - \\ \bar{X} \text{ OF STABLE MEMBERS OF ORIGIN RELIGIOUS STATUS} \end{array} \right] - \left[\begin{array}{l} \text{SWITCHER'S STATUS LEVEL} \\ - \\ \bar{X} \text{ OF STABLE MEMBERS OF DESTINATION RELIGIOUS STATUS} \end{array} \right]$$

A positive index value indicates that the difference between the switcher's status and the average status of his or her religion of origin (stable members) is greater than the difference between his or her status and the average status of his or her religion of destination, giving some support for the socioeconomic hypothesis. If there is no relationship between religious mobility and socioeconomic status, we would expect negative values, since the

individuals who move out of an origin religion should not differ systematically from those who stay (given, of course, the assumption that members of denominations in general are socioeconomically homogeneous). Note that an index value of zero for an individual would indicate that he or she was about halfway between the statuses of the origin and destination religions.

The average values for the index for each of the three statuses, listed by *destination religion* of the switchers, are given in Table 10. The average of \$578, for

Table 10. Socioeconomic Index of Difference between Switcher's Status and \bar{X} Status Levels of Religions of Origin and Destination, for Religiously Mobile Heads of Household, 1975-76 NORC Data, Listed by Religion of Destination

	Occupational		
	Income	Prestige	Education
High SES	\$ 578.	1.8	.38
Medium SES	357.	.4	.27
Baptist	223.	.2	-.3

Prot., No Denom.	-117.	.3	.07
Catholic	-412.	-.3	.16
Jewish	-841.	-3.7	-1.4
Other	-1,698.	-1.1	-0.65
None	- 691.	-0.2	-0.13

¹² David L. Morgan suggested the use of this type of index.

example, for switchers into the High Status denominations, indicates that switchers were 578 dollars farther away from their religion of origin status level than they were from their religion of destination status level (i.e., they were, on the average, closer to the status of their destination religion than their origin religion).

It can be seen that positive index values for income result for switchers into the four Protestant denominations, but that negative index values result for switchers into Catholicism, the Jewish faith, the two areligious categories, and the Other category. These negative numbers suggest that income is *not* a primary explanatory factor in the shift to these religious groupings.

The same general pattern holds for occupational prestige. Note that the relationship between prestige of switcher and the average prestige of destination members is particularly strong for those moving into the High and Low Status categories. The index values for education are somewhat different: Switchers into the Baptist category are slightly more similar to their religion of origin educational status than the average education of stable Baptists. And, in a pattern unlike that evidenced for the other two indicators, switchers into the Catholic faith are closer in education to Catholics than to the members of their origin religion categories.

In general, the findings in Tables 6 through 10 indicate that movement to various Protestant denominations is congruent with what would be expected if

socioeconomic status is an important factor in the move, and that movement to the other five religious categories is more likely to be based on other factors.

We can check these conclusions in a somewhat different fashion by analyzing the contributions that each of the religion variables (religion of origin and religion of destination) make towards explaining the variance in the three socioeconomic indicators, for switchers only. Presumably, if the religious switch is not made for socioeconomic reasons, the religion of origin of switchers will be significantly related to their socioeconomic status. We would also predict under this null hypothesis of no relationship between socioeconomic status and religious mobility that the SES of switchers would be randomly distributed among the religion of destination choices, and that, as a result, knowledge of a switcher's religion of destination would not help us predict his or her current socioeconomic status. Note that these procedures are different from the previous analyses which utilized information on the stable members of the religious groupings. Here we are dealing only with the simpler question of a relationship between the choice of a religion of destination for a religious switcher and that switcher's socioeconomic status.

The analysis of variance procedures used here check these hypotheses by analyzing each of the two main effects after the effect of the other independent variable has been taken into account. The results are displayed in Table 11 and show significant main effects for current religion

¹ Significantly greater than zero ($p < .01$).² Difference between r 's for urban and rural residents not significant ($p > .05$).³ Difference between r 's for South and Non-South residents not significant ($p > .05$).

of switchers for all three statuses, and significant effects of religion of origin only for education. The significant main effects of current religion indicate that knowledge of the destination religion of a switcher helps explain variance in the socioeconomic status of that individual; i.e., that switchers are socioeconomically differentiable by their destination religion. This supports the hypothesis of a relationship between religious mobility and socioeconomic status.

An additional way of summarizing the relationships between switchers' socioeconomic levels and the socioeconomic levels of their destination religions is with correlation coefficients. Categories can be coded according to the average educational, occupational prestige, and income levels of their *stable members*. The relevant socioeconomic status level of religious switchers then can be correlated with the destination religion of these switchers, coded by stable members' SES levels. The resulting statistics give an indication of the relative strength of association between a switcher's status and the status of the stable members of his or her destination religion. The calculated correlation coefficients and related statistics are reported in Table 12, for the three socioeconomic statuses.¹³ As can be seen, the correlation coefficients for each of the three relationships (education, occupational prestige, and income) are positive and of moderate strength (all of these relationships are statistically significant at the .01 level). Thus, as we would predict from the tables we already have exam-

ined, there is a positive relationship between the status levels of switchers, and the average status of the membership of these switchers' destination religions.

We can predict differences by subgroups in our sample. We can assume that rural residents might be under more pressure than urban residents to bring their religious affiliations in line with their socioeconomic status (see Nelson and Snizek, 1976; Roof, 1976). The relative *gemeinschaft* existence in rural communities, wherein all aspects of an individual's life are known to all of his or her fellow residents, would suggest these pressures towards status consistency. The relative *gesellschaft* nature of urban existence, on the other hand, might suggest that an individual could maintain a religious affiliation whose socioeconomic characteristics were disparate from the individual's socioeconomic status, without suffering from the pressures of inconsistent evaluations. Similarly, in line with research which supports the idea of a southern "culture" independent of most confounding variables (Middleton, 1976), we might predict that the socioeconomic status-religious affiliation congruence would be stronger in southern states than in nonsouthern states. Both of these hypotheses have been tested in Table 12.¹⁴

As can be seen, the biggest differences occur between the southern residents and those residents of the rest of the United States, particularly in the relationships between educational level of the switches

¹³ Switching to *nonreligious* categories were excluded from data used in the calculation of these coefficients.

¹⁴ Urban dwellers are those individuals who report living within a Census Bureau defined SMSA, while southern dwellers are those who live in the South Atlantic, East South Central and West South Central regions of the United States as defined by official Census Bureau classifications.

Table 13. Religious Mobility for Each Category of Occupation of Origin and Current Occupation, Males and Unmarried Female Respondents (Excluding Widows), 1975-76 NORC Data

Occupational Category of Father	Current Occupational Category					
	Upper White-Collar	Lower White-Collar	Upper Blue-Collar	Lower Blue-Collar	Farm	
Upper White-Collar	7% 72% (116)	5% 69% (42)	4% 64% (28)	2% 70% (43)	0 67% (3)	5%
Lower White-Collar	10% 58% (31)	4% 72% (25)	8% 85% (13)	6% 67% (18)	0 0 (0)	7%

Lower Blue-Collar	10% 71% (69)	4% 74% (47)	10% 65% (69)	4% 73% (157)	0 100% (2)	7%
Farm	17% 61% (46) 10%	22% 72% (18) 8%	12% 72% (58) 8%	4% 79% (81) 4%	9% 76% (54) 8%	11%

Note: Top percent figure represents religiously upwardly mobile; middle percent figure represents percent religiously stable; bottom figure represents N of cell. Figures at right side and bottom of table represent row and column marginal percentages upwardly mobile, respectively.

and the educational levels of the destination religions, although all differences are statistically insignificant.

We turn briefly now to a more direct examination of the relationship between upward social *mobility* and religious mobility. We must limit our analyses here to male and single female respondents, since we have no information on the parent's occupation status of the spouses of respondents, and since we assume it is the husband's occupational mobility in these data (particularly for older respondents) which defines the household's status and which would therefore be expected to be related to the religious shift.

Respondents and their fathers' occupations were categorized into five categories (see Knoke, 1973: 1452): upper nonmanual (professional, technical and kindred, business and managerial); lower nonmanual (clerical, sales and kindred); upper manual (craftsmen, foremen and kindred); lower manual (operatives, service workers and laborers, except farm and mine); and farm (farmers and farm laborers).

Religious mobility of the respondents was developed into a five category scale: religiously upwardly mobile; religiously stable; religiously downwardly mobile;

other mobility; and mobility into the No Religion category.¹⁵

Table 13 displays the frequency distributions for this religious mobility variable for each combination of occupation of origin (defined as father's occupational status) and respondents' occupation at the time of the survey.

It is apparent that individuals occupationally upwardly mobile are more likely to have been religiously mobile than individuals either occupationally stable, or occupationally downwardly mobile. Note for example that the average percent religiously upwardly mobile for all respondents raised upper manual is about 7%. Yet the 126 of these individuals who were mobile into the nonmanual occupational

¹⁵ The Upward Religious Mobility category included those who switched into the High Status denominations from any other religious group, those who switched into the Medium Status denomination from any religious group other than High Status group, and those who switched into the Baptist category from the Low Status denominations. The Downward Religious Mobility category included those who switched into the Medium Status denominations from the High Status denominations, and those who switched to the Baptist denomination from the High or Medium Status denominations, and those who switched into the Low Status denominations from the High, Medium or Baptist denominations. The other category included all other switches.

categories were between 10% and 12% religiously mobile. The same patterns obtain for the other ten cells of occupationally mobile individuals, which, with one exception, display religiously upward mobility percentages higher than we would predict from an examination of the relevant occupation of origin marginal percentages. Interpretation of the grouped or averaged percentages by mobility category must be interpreted with caution and with the type of examination of row and column effects discussed above. As can be seen, the upward mobility factor for occupationally mobile individuals is about 10%, for stable and downwardly occupationally mobile individuals, about 5¼% to 5½%.

Marriage. An explanation for religious switching which is testable using the 1975-76 data concerns religiously heterogamous or potentially religiously heterogamous marriages and the resulting switch of one partner to the religion of the other (see Warren's illuminating discussion, 1970: 143-151). In instances where only one partner has switched religion, it can be quickly determined using our 1975-76 data whether or not the switching spouse moved to the stable religion of nonswitching partner.

All married switchers were included in this analysis (the basic sample was used, not Head of Households). There were, as can be seen from Figure 1, 279 male married switchers and 310 female married switchers (78% of the total of 756 switchers). These were further divided into subgroups according to the ultimate homogamy of the married couples' religions at the time of the survey.

If switchers change religions in order to move into the religion of their spouse, then we would predict a large percent of married switchers to (1) have stable spouses, and (2) be in the same religion as that stable spouse. As can be seen, 41% of all female married switchers and 39% of all male married switchers in fact met these requirements of having moved into the religion of the stable spouse.

It is interesting to note that 36.9% of male switchers and 41.6% of female switchers had spouses who also switched.

Most of those double switching couples moved into the same destination religious categories (82% of male and 72% of female married respondents). Finally, as can be seen, 29% and 28% of male and female switchers, respectively, ended up in different categories from their spouse (most of these, further analysis indicates, were situations in which the switcher moved into the No Religion category).

It should be reemphasized that even this act of switching to a stable spouse's religion does not preclude the possibility that the switch had something to do with socioeconomic (or other) factors. As Warren (1970) points out, the decision of a spouse to hold firm in his or her religious beliefs and for the other spouse to switch to this religion may be based on the socioeconomic composition of the ultimate destination religion. This would be particularly true if a type of "anticipatory" mobility process were at work in which couples at marriage began to make decisions based on plans for future socioeconomic positioning.

Age. One variable reasonably related to the religious shift might be the age of the individual involved. Age should not be considered an exogenous explanatory variable in and of itself, but it presumably stands for, and provides a mechanism for isolating, processes which have affected certain groups of individuals. In general, if we find differences in a dependent variable by age groupings in one cross-sectional sample, they either reflect the fact that the particular cohort sampled lived through some unique historical circumstances (such as the Depression for those 55 and older; World War II for those 45 and older; or the Vietnam years for those individuals now 25 to 35) or they can reflect the fact that all individuals pass through certain stages at certain time-specific points in their lives.

Wuthrow (1976) argues that changes in religious behavior and affiliations in recent years, specifically the increasing rate of apostasy, are a reflection of the former process: a specific generational circumstance which affected individuals growing up in the 1960s, but which is not necessarily a process which has affected or will

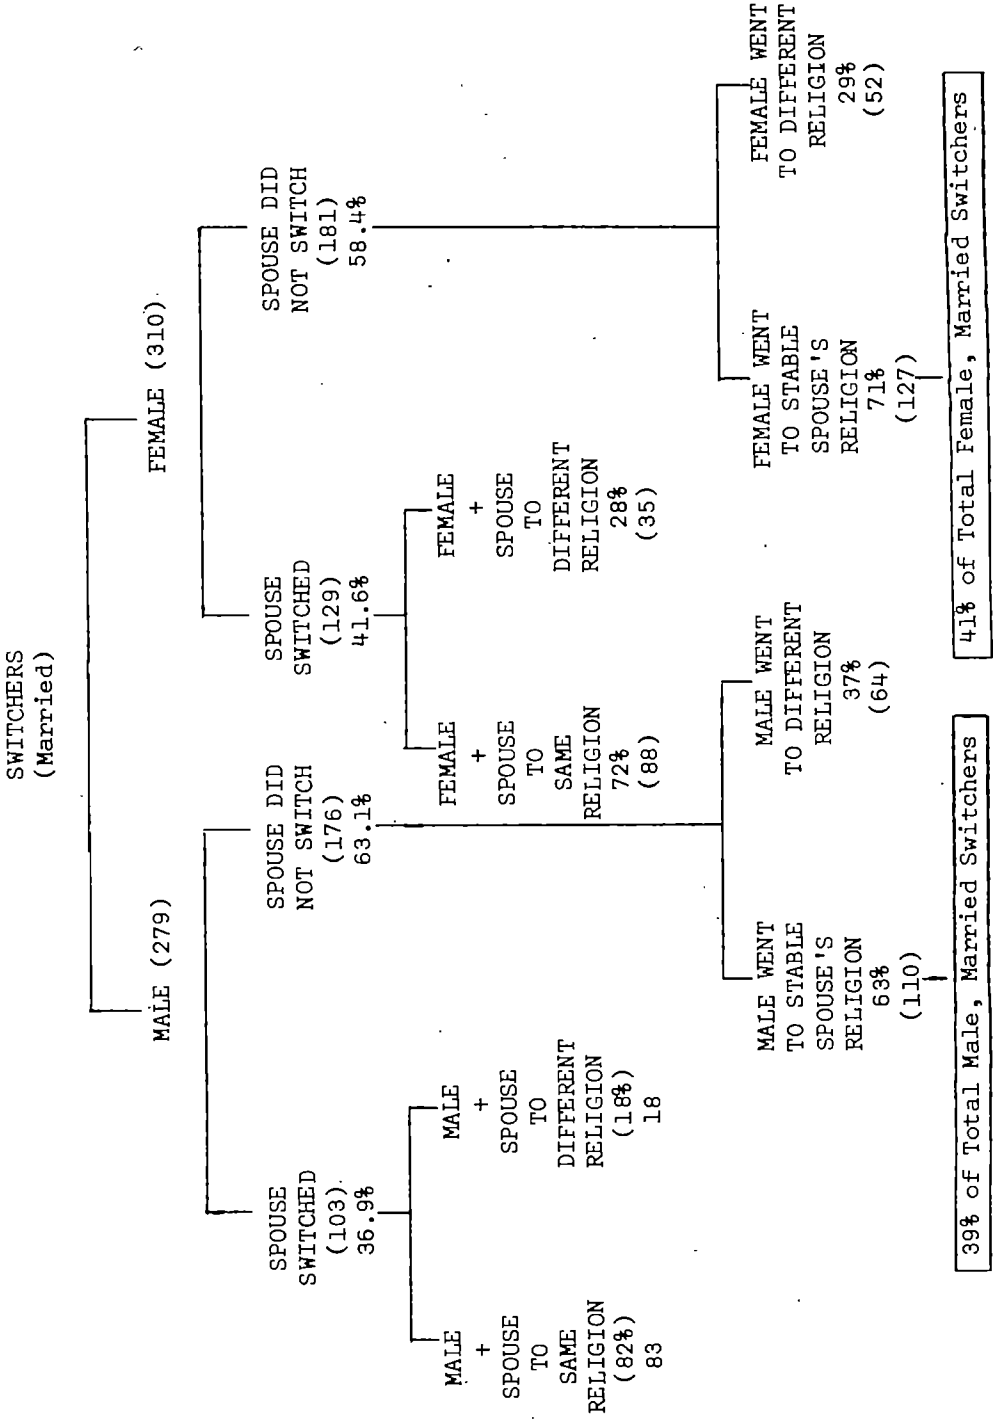

Figure 1. Breakdown of Relationship between Religion of Switcher and Religion and Mobility of Spouse, Religiously Mobile Sample, 1975-76
NORC Data.

affect every cohort of young individuals (1976: 861-3). Wuthrow's discussion would be useful in explaining the contradiction between Stark and Glock's data on mobility into the No Religion category, collected in 1965, and the data we have analyzed from 1975-76. We found a high degree of immobility to the No Religion category, while Stark and Glock found little evidence of such a trend. If Wuthrow is correct, these data could reflect the fact that Stark and Glock did not have significant members of the 1960s "countercultural" generation in their data set, and the 1975-76 data set did.

What do the 1975-76 data tell us about age? Table 6 presents the mean age for each subgroup created by the intersection of the religions of origin with the religions of destination, for the 1975-76 data. It is apparent that we find support for the trend documented by Wuthrow, and by Roof and Hadaway (1977: 411). The mean age of every group of individuals who have switched into the No Religion category is younger than the age of the religions of origin of these individuals. As can be seen from the column means, the No Religion category thus has the lowest mean age of any of the nine religious categories of destination. This age difference suggests that the group of switchers to No Religion is disproportionately composed of young people.

It is interesting to speculate about the future of this group of individuals (i.e., those now in the No Religion category). If their apostasy is a generational phenomenon (Wuthrow, 1976: 862), then we might predict that it would follow them throughout their life cycle, with the result that a significant percentage of population samples taken over the next 50 years will remain in this No Religion category. But, it could be argued that this apostasy effect, while occurring to a specific generation, may still be subject to some age specific patterns, and that as these individuals move into their thirties and have families and children, we will find them returning to religion. This would result in a rather dramatic decrease in the No Religion category over the next years, assuming that the cohort coming of age in the 1970s will not experience a similar generational

countercultural effect which will drive them from the churches like their brothers and sisters of the 1960s. Future data will resolve these issues.

DISCUSSION

What are the implications of these data for the study of religion in America and the general attempt to arrive at theories of the relationship between religion and society? First, it is important to note that while the data show some fluidity in religious affiliation in the United States, there is really not as much mobility as we might expect. Recall that of the approximately 30% of those surveyed in 1975-76 who switched religions, about 38% had moved out of the religious system altogether. This leaves only about 18.6% of all Americans surveyed who have effected a move from one religion to another religion. And of this movement, fully 61% is intra-Protestant, as opposed to movement among the major religious groupings (Catholic, Jew, Protestant, and other). Overall, then, it is actually a rather small percentage of Americans who change from one religion to another during their lifetimes, which means that the best single predictor of an individual adult's religious preference is still the simple knowledge of his or her parent's religion.

These data on the relative stability of our religious affiliations from generation to generation lead to interesting interpretations. It is clear that we do not live in a nation of sects, with voluntary membership produced by conscious, within-generation changes. We live instead in a nation of church-like religious groupings in which membership is largely a between-generational hand-me-down, produced from within. From at least one perspective, this stability is not very encouraging, and is not particularly a state of affairs which we are happy to accept, as Skinner (1953:9) has noted:

Though we observe that Moslem children in general become Moslem while Christian children in general become Christians, we are not willing to accept an accident of birth as a basis for belief. We dismiss those who disagree with us as victims of ignorance, but we regard the promotion of our own religious

beliefs as something more than the arrangement of a particular environment.

Political scientists long have used data on the intergenerational stability of political party preference as evidence of the failure of the American electorate to be individually and rationally concerned with candidates and issues involved in elections. Similarly, one could conclude pessimistically that the present evidence argues against the notion that Americans pick and choose their religious affiliation on the basis of some well-thought-out and *theologically* based criteria.

From another perspective, however, this stability of religion across generations does not necessarily reflect a total absence of theological contemplation. No religion can operate in a social vacuum. A religion serves the personal and social needs of its members. Adherents to a religion have social and economic positions within their society, and pressures exist which cause individual's social positionings to be congruent with both the theology and the organizational facets of their religion. Thus, to the extent that children inherit their parents' social and economic characteristics, we would assume that their parents' religious affiliation would continue to be useful. And the recognition of this usefulness, and the resulting decision to remain in one's parents' religion, could occur not just by default, but from a conscious, thoughtful consideration of religion and its role in one's life. It could be, in other words, that some children remain in their parents' religion *precisely* as a result of careful deliberation in which they conclude that what is good for their parents is good for them, for the same reasons.

This second perspective leads us to predict that the religious needs of the individual will not be as well met if the individual has a social and economic status different from that of his or her parents' and thus different from that of the church in which the individual had been raised. The data reviewed in this paper, as we have seen, give support to this notion. Those who switch settle in religions which match their currently reported socioeconomic status more closely than did the socioeconomic characteristics of the reli-

gions which they left. And there is some evidence to support the idea that upward socioeconomic mobility is related to upward religious mobility. We have no data on the precise point in the switcher's life cycle when the switch is made, as we pointed out, so we have no conclusive evidence that the switch was made into a denomination which matched some already achieved status. It could be that the shift caused the socioeconomic status level differential. Nevertheless, the correlational evidence is support for the general idea of the importance of the relationship between socioeconomic status and religious affiliation, and for the idea that changes in status may lead to changes in religion.

A healthy percentage (40%) of married switchers moved to the religious affiliation of their stable spouse, data which support the idea of the importance of marriage in the decision to shift. But we are still left with the necessity of determining the basis for choosing one spouse's religion over the other. Presumably, as we noted, this decision could be based on socioeconomic (or other) grounds.

The data on age support what is becoming the conventional wisdom: the movement out of religion altogether is to a large degree a function of age. The average switcher to the No Religion category was considerably younger than the average age of the members of his or her religion of origin. We will have to wait for future years' analyses to see if this will be a recurring generational phenomenon of the young, or if it is a phenomenon which belongs specifically to a generation of young people who came of age in the 1960s.

Some of our data contradict commonly held notions about the process of religious change in this country. In particular, it is obvious that despite appearances to the contrary, Baptists are growing as a religious group in spite of the fact that they are not converting new members at a high enough rate to replace departing members. Similarly, the High Status denominations are losing ground overall despite the fact that they enjoy a positive net migration factor. Only in the ranks of the Medium Status denominations (most par-

ticularly the Methodists) do we find support in the data for the concerns of these church members and leaders over their shrinking numbers: they are losing membership due to negative migration factors.

As we noted at the outset of this paper, we have not directly investigated what might seem the most obvious reasons of all for the religious shift: conscious, rational, theological decisions. And, as we also noted, we have not looked at specific, localized factors no doubt somewhat important in the shift: the geographic locations of a church, specific congregations and their particular appeals, specific ministers, and other particularistic factors which would not be measured in a survey of the types used in these investigations.

A central question which remains when we ponder future research on the religious switcher is the potential usefulness and validity of survey research and/or intensive interview methods in which respondents are asked directly why they changed religions. This method would seemingly be a more obvious way of establishing explanations for religious mobility than the indirect method used in this paper of ascertaining relationships between religious mobility and other, presumably explanatory sociological variables of interest.

An example of such direct interrogation available in the literature is the Catholic Digest survey of Marty et al. (1968: 304-6). Individuals were asked: "How did you happen to change [religions]?" The respondents chose one of the following answers: "Took the religion of my husband or wife," "Moved to where my denomination had no church," "Liked religious beliefs of another church better," "Influence of friends, relatives, etc.," "Found religious beliefs of former church unsatisfactory," "Disagreeable experience with clergyman," and "All other reasons." Fully 50% of the respondents who had changed religions chose the first two of these explanations for their shift. How useful is this information? One major determination of the switch, socioeconomic factors, is not even listed among the responses. The reason for this may be that individuals do not have unique access to the reasons for their switch (or for any of their own behaviors) and/or that they

tend to give socially acceptable reasons when forced to make an explanatory comment on their behavior (Nisbett and Wilson, 1977). The validity of such self-reports are problematic until shown otherwise. Future research on the religious switch should perhaps move in this direction, but with a healthy regard for the possible invalidity of such self-diagnoses.

MANUSCRIPTS FOR THE ASA ROSE SOCIOLOGY SERIES

Manuscripts (100 to 300 typed pages) are solicited for publication in the *ASA Arnold and Caroline Rose Monograph Series*. The Series welcomes a variety of types of sociological work—qualitative or quantitative empirical studies, and theoretical or methodological treatises. An author should submit three copies of a manuscript for consideration to the Series Editor, Professor Robin M. Williams, Jr., Department of Sociology, Cornell University, Ithaca, New York 14853.

THE SOCIAL ORGANIZATION OF THE AMERICAN BUSINESS ELITE AND PARTICIPATION OF CORPORATION DIRECTORS IN THE GOVERNANCE OF AMERICAN INSTITUTIONS*

MICHAEL USEEM

Boston University

American Sociological Review 1979, Vol. 44 (August):553-572

Recent analysis suggests that the American business elite is differentiated along an "inner group" axis. At one end of the axis are those business people who are primary owners or top managers of several major corporations, collectively labeled the *inner group*, while at the other end are those who are connected with only a single major corporation. It is reasoned that, by virtue of their multiple corporate connections and the resulting transcendence of parochial corporate interests, inner group members would be more often involved in the governance of other institutions than would be other members of the business elite. Institutional governance includes the occupancy of top administrative posts and governing and advisory board positions of three types of institutions: nonprofit, nongovernment organizations, such as economic development and cultural organizations; local, state, and federal agencies; and major business policy associations. Drawing on a set of 2,003 directors of the nation's largest 797 corporations in 1969, and on director biographical information acquired from several sources, this study found that inner group members are substantially more likely, compared with other members of the business elite, to be involved directly in the governance of a range of institutions. Moreover, available evidence also indicates that the higher participation rate of inner group members is at least partly a result of their capacity to mobilize greater corporate resources and their involvement in a common, transcorporate social network. The evidence presented tentatively supports the thesis that the American business elite is differentiated along an inner group axis, at least with respect to the selection of business people to assist in the governance of other institutions. The inner group may be an important source of political leadership capable of promoting the more general interests of the entire capitalist class.

If American business has successfully penetrated the economies of many societies abroad, it has been no less successful in penetrating noneconomic institutions at home. Governing boards of museums, high-level government offices, and public agency advisory panels are filled with businesspeople, though rarely is their dominance complete. Studies of

the occupants of the governing circles of nearly all American institutions, whether public or private nonprofit, invariably reveal that the surest career for entry into such circles is corporate management. The largest single occupational grouping is virtually always business, with the professions a close second; all other occupations, comprising the vast majority of the U.S. labor force, divide among them the few remaining positions.¹

While the business presence in governing positions is unimpressive to some observers who view it as largely symbolic, for others it is a crucial datum, indicative of capitalist control of both private and

Of great value for this analysis were the efforts of a number of people in acquiring data on the U.S. business elite and their generous willingness to make the data available. For the names of the corporate directors used in the present analysis, I would like to thank Joel Levine, Peter Mariolis, and Michael Schwartz; for business policy association membership information, I am appreciative to Paul Blakely, Phillip Bonacich, G. William Domhoff, and Ben Smith. Gladys Delp and Linda Trenholm provided invaluable research assistance, and the U.S. National Science Foundation provided financial support (grant number SOC77-06658). I would also like to thank Howard Aldrich, Jerome Karabel, S. M. Miller, and two anonymous reviewers for helpful suggestions. An earlier version of this paper was presented at a 1978 conference sponsored by the European Group for Organizational Studies, and

special thanks are due to Elina Almasy, Jane Marceau, and Richard Whitley.

¹ For examples of studies reporting the occupational composition of those occupying top administrative positions and serving on governing boards for public and private nonprofit organizations, see Freitag (1975) for top federal government appointees, Hartnett (1969) for college and university governing boards, DiMaggio and Useem (1978) for arts organization governing bodies, and Landau (1977) for hospital trustees.

public life. Domhoff's (1970) "higher circles," composed chiefly of corporate executives, primary owners, and their descendants, constitute, in his view, "the governing class in America," for these businesspeople and their families dominate the top positions and governing boards of foundations, universities, and federal agencies. Drawing on studies of the social origins and prior occupations of government officials, Miliband (1969:47) reaches a similar conclusion. While granting that there does exist a "plurality of economic elites in advanced capitalist societies," he nonetheless finds that

"elite pluralism" does not . . . prevent the separate elites in capitalist society from constituting a dominant economic class, possessed of a high degree of cohesion and solidarity, with common interests and common purposes which far transcend their specific differences and disagreements.

This thesis of business dominance of the government has been challenged, of course, by many analysts who reject not only the political significance attributed to the dominance by businesspeople of positions of governance, but also the presumed class unity upon which the businesspeople's influence allegedly rests. Illustrative of this counterinterpretation is Daniel Bell's (1961:62-3) thesis that the disintegration of family capitalism in America has thwarted the emergence of a national "ruling class." He contends, for instance, that "there are relatively few political issues on which the managerial elite is united" now, since "in the last seventy-five years the established relations between the system of property and family . . . have broken down." The consequence has been a "breakup of 'family capitalism,' which has been the social cement of the bourgeois class system." Upon reviewing more recent evidence, Berg and Zald (1978:137) argue similarly that "businessmen are decreasingly a coherent and self-sufficient autonomous elite; increasingly business leaders are differentiated by their heterogeneous interests and find it difficult to weld themselves into a solidified group."

While these two perspectives presume radically different roles for the businesspeople who do serve in governing

positions with public and private institutions, there is at least agreement that businesspeople are disproportionately present. Yet both approaches provide little detailed guidance regarding the question of which businesspeople actually assume the leading roles in the governance of these institutions. This can be attributed, in part, to the relative lack of attention in both perspectives to the internal social organization of the capitalist class. Class organization deserves special attention, however, since it can have a decisive bearing on which businesspeople come to assume roles as "spokespersons" for business. And, since businesspeople vary in the kinds of policies they would urge on other institutions given the opportunity, the type of businesspeople who do acquire leadership positions can have implications for the actual policies adopted and, ultimately, the business interests promoted.

Building on recent analyses of the internal social organization of the American capitalist class, this paper proposes that the businesspeople most likely to become involved in the governance of other institutions occupy a distinctive class "location," and new evidence is presented to test the validity of this thesis.

THE SOCIAL ORGANIZATION OF THE CAPITALIST CLASS

The *capitalist class* consists of those who are the primary owners and top managers of major business firms; in this paper it will be used interchangeably with *business elite*. The use of the latter term is purely a matter of linguistic convenience, and it does not connote that the analysis is rooted in an "elitist" theoretical framework. The social organization of the capitalist class, or business elite, consists of the formal and informal networks of economic and social relations among the corporate owners and managers. *Institutional governance* refers to the occupancy of positions with high influence in, or formal authority over, public and nonprofit private institutions, such as government agencies, schools, and foundations. Positions of influence or authority include governing boards, advisory boards, and top administrative posts.

The social organization of the business elite is most likely to be determined by the nature of the formal business roles occupied by elite members (e.g., officer, primary owner, or director) and characteristics of the firm with which the position is associated (e.g., the firm's size and product). Other factors, such as government taxation policies and regulation of the securities market, also impinge on elite social organization; and the organization itself possesses a degree of autonomy, allowing for evolution according to its own internal dynamics. Nevertheless, the critical determinant is the structure of the economy, and, thus, the social organization of the business elite should be closely related to the divisions, alliances, and interdependencies among and within the major business firms in American society.

One of the most significant elements of economic organization with implications for class social organization is the sharing of directors by several major corporations. Boards of directors are legally and formally responsible for the operation of a firm and the protection of owner interests (they are elected by the shareholders; Bacon, 1967; Zald, 1969). Boards vary in size from three to more than 30 seats, though typically they include from 10 to 15 members. Frequently, seats on two or even more boards of directors are occupied by the same person. In 1969, for instance, 8,632 individuals served as directors of the nation's largest 797 financial and nonfinancial corporations, and nearly one-fifth (1,572) of these were "interlocking" directors, serving simultaneously on the boards of at least two of the corporations (Mariolis, 1975:433). The reasons for the establishment of these interfirm ties have been the subject of considerable analysis, but the origins of the interlocking directorate need not concern us directly here (see Dooley, 1969; Mace, 1971; Burch, 1972; Pfeffer, 1972; 1974; Allen, 1974; Bearden et al., 1975; Koenig et al., 1976; Sonquist and Koenig, 1976; Bunting, 1976). What is of significance for the present argument is that members of the business elite who sit on several boards of directors are placed in a unique position compared with other

members of the elite who are responsible for the operation of only a single firm. Interlocking directors are in a position to recognize—and help reconcile—the problems of several firms, often operating in very different environments.

Interlocking directors constitute a major part of a broader segment of the capitalist class that, following Zeitlin et al. (1974), we will label an *inner group*. The inner group consists of members of the business elite who have significant "connections" with at least several major corporations. Significant connections are those which involve the capacity to shape corporate policy, and include substantial ownership in a firm, service as a director or officer, and close kinship with those holding the former connections. The inner group is not limited to interlocking directors, but interlocking directors do constitute a critical component and we will focus on them here. "Inner group" is a metaphor and the boundary between it and the remainder of the capitalist class is not sharp. Indeed, it is more appropriate to think of its members not as a distinct group at all, but rather as clustered near the end of a continuous differentiating axis within the capitalist class. This axis of *inner group centrality* ranges from those who are connected with a single major firm to those with two connections, three connections, and at the far end of the axis, many connections.

PREVIOUS RESEARCH ON THE INNER GROUP

A fully elaborated analysis of the social organization of the American business elite and the structure of the inner group is not available, but elements of such a formulation have appeared in a number of studies. Outlines of the inner group thesis even date back to Mills's (1956) *Power Elite*. A major premise of Mills's analysis is that American capitalism is marked by increasing centralization and concentration. This process, in Mills's view, has led to the emergence of a new breed of corporate executives committed to industry-wide concerns and not simply the interests of their own firm. Moreover, a fraction of these executives take an even broader

view of business problems: "They move from the industrial point of interest and outlook to the interests and outlook of the class of all big corporate property as a whole" (Mills, 1956: 121). Mills identifies two features of business organization which are primarily responsible for this transition in outlook. First, the investments of a small circle of top managers and owners have become dispersed among a number of firms. As a result, "the executives and owners who are in and of and for this propertied class cannot merely push the narrow interests of each property; their interests become engaged by the whole corporate class" (Mills, 1956: 121). Second, the emergence of an extensive network of interlocking directorships among the major corporations has also meant that a number of managers have assumed responsibility for the prosperity of several corporations, and thus those holding several directorships constitute "a more sophisticated executive elite which now possesses a certain autonomy from any specific property interest. Its power is the power . . . of class-wide property" (Mills, 1956: 122).

Features of the inner group thesis can also be found in Maurice Zeitlin's (1974; 1976) more recent assessment of theory and research on the American capitalist class. Centralizing tendencies akin to those discussed by Mills are, Zeitlin tentatively suggests, generating an overarching unity within the business elite, and prominent among these forces is "the establishment of an effective organizational apparatus of interlocking directorates" cutting across both financial and industrial sectors. This apparatus may be an important ingredient in the heightening of "the cohesiveness of the capitalist class and its capacity for common action and unified policies" (Zeitlin, 1974: 1112). The national network of owners and managers with diverse corporate investments and positions is viewed by both Mills and Zeitlin as a progressive force in the capitalist class; and one which is increasingly in a position to impose its policies on the remainder of the class. The growing concentration of economic power in this network also has been discerned by a recent Congressional Study of corpora-

tion interlocks; indeed it anticipates that the "interlocking management device" could lead to a situation in which "inordinate control over the major part of the U.S. commerce would be concentrated in the hands of [a] few individuals," resulting in the possibility that "an 'inner group' would control the destiny of American commerce" (U.S. Congress, 1965:225-6).

A dominant theme in these examinations of the American business elite is the special role played by the top managers and primary owners with multifirm connections. Capitalists with ties to several, often disparate companies necessarily become concerned with the joint welfare of all the companies, and these concerns may come to coalesce with the general welfare of a broad spectrum of companies and their owners and managers. "Even more than other large corporation executives," suggest Zeitlin et al. (1974: 4),

those who sit at the center of the web of interlocking directorates must have an outlook and execute policies that, while yet serving particular and more narrow interests, conform to the general interests of the corporate community and of the principal owners of capital within it.

The inner group, in short, may constitute a special segment of the capitalist class, if a *class segment* can be defined as a subset of class members sharing a social location with partially distinct interests. Though the common concern with capital accumulation unites the inner group with the remainder of the capitalist class, at the same time the inner group's greater stake in class-wide interests sets it apart.

There is already some systematic evidence to enhance our confidence that the inner group does, indeed, constitute a distinct class segment. As a consequence of the divergence of the secondary interests of the inner group from those of the remainder of the class, members of this class segment can be expected to evolve partially distinctive ideologies, social circles, and patterns of intergenerational reproduction. Though the methodologies and setting vary widely, available studies reveal that the inner group does exhibit at least some of the traits expected of a separate class segment: those with multiple-firm connections, compared with other

members of the business elite, tend to be descendents of business elite families (Soref, 1976), individually wealthy or members of wealthy families (Zeitlin et al., 1974; Useem, 1978a), mutually acquainted (Perrucci and Pilisuk, 1970; Higley et al., 1976: 231-9; Koch and Labovitz, 1976), members of exclusive metropolitan social clubs (Koenig et al., 1976; Soref, 1976; Useem, 1978a), and influential in the affairs of local community organizations and in some colleges and universities (Perrucci and Pilisuk, 1970; Koch and Labovitz, 1976; Ratcliff et al., 1979; Useem, 1978a; 1978b).

THE INNER GROUP AND INSTITUTIONAL GOVERNANCE

A distinctive political role for the inner group is expected as well. While the political activity of a class segment can take many forms, this investigation will concentrate on a single political element (and, thus, our discussion is largely restricted to it). We will focus on the rate of business participation in institutional governance. It is hypothesized that the inner group will be substantially overrepresented, compared with other class members, in positions with direct influence on the policies of other institutions. The inner group's higher degree of political engagement is anticipated for several reasons.

First, the multiple corporate connections of inner group members tend to foster the formation of informal transcorporate networks. The heightened visibility associated with involvement in these networks should make inner group members more likely candidates for openings on governing boards and advisory bodies. The multiple corporate connections also place inner group members in an exceptionally good position to help mobilize the resources of many firms on behalf of policies they favor—and institutions whose governance they assist—making inner group members preferable to other businessmen when appointments to positions of governance are decided.

Second, inner group members also are expected to be especially prominent in institutional governance because of the integrative position the inner group holds

within the capitalist class. Like other social classes, this class contains major economic cleavages that can generate sharply opposed views on the policies most appropriate for other institutions to pursue. Certain federal government policies, for instance, may benefit large firms at the expense of smaller firms, banks at the expense of industrials, and certain sectors, such as oil or military goods, at the expense of others. These divisions over secondary economic interests can engender conflicts that potentially threaten the primary economic interests shared by all corporations. By virtue of their connections with several corporations and their involvement in a network of those associated with still other corporations, inner group members are uniquely situated to identify the policies that would foster the more general interests of many, if not most, major corporations. Thus, inner group members may constitute attractive "compromise" candidates when various segments of the capitalist class compete over who among their ranks would be appropriate business leaders. From the standpoint of the outside institutions as well, the capacity of the inner group to transcend the parochial interest of specific firms and sectors makes inner group members especially suitable business representatives.

Third, by virtue of their stronger connection with the primary holders of corporate ownership, inner group members are also more likely to be promoted for governance positions. Evidence from both the U.S. and Chile indicates that, compared with other members of the business elite, those holding multiple corporate directorships are more likely to be primary owners themselves or members of extended families with widespread holdings (Villarejo, 1962; Burch, 1972; Zeitlin et al., 1974; Soref, 1976; Useem, 1978a). The reasons for this intertwining of position and ownership need not be entered into here, but one consequence is that inner group members who are not themselves primary owners are especially likely to receive primary owner political backing. And, to the extent that primary owners, both those who also serve as multiple directors and those who do not, exercise

disproportionate influence on decisions within the corporate community because of their dominant wealth position, their support and power should further heighten the probability that inner group members become overrepresented on the rosters of institutional governance.

While previous studies have not explicitly examined the role of the inner group in American institutional governance, research on the occupants of top federal positions consistently reveals that they are over-drawn from the ranks of directors and executives of the largest corporations (Mills, 1956; Miliband, 1969; Kolko, 1969; Domhoff, 1970; Mintz, 1975; Freitag, 1975; Dye, 1976). Many of the directors and executives of major companies hold multifirm connections, and it is possible that these findings largely reflect disproportionate recruitment of inner group members, rather than members of the business elite per se, into top government positions. This question has not been directly addressed in previous empirical work on the U.S. (see Zeitlin et al., 1976, for empirical work on a related question in Chile), however, and it will be the primary focus of the present inquiry.

In sum, then, prior research suggests that the inner group does constitute a distinctive segment of the capitalist class, and it has been argued here that the position of the inner group in the social organization of the class is likely to lead its members to take a particularly active role in institutional governance. It is expected, therefore, that interlocking directors will more often occupy oversight positions in public and private nonprofit institutions than will other members of the business elite.

RESEARCH DATA

The business elite selected for analysis consists of those who were directors of the 797 largest U.S. corporations in 1969. The largest firms were those identified by the standard and generally accepted annual ranking conducted by *Fortune* magazine. The firms were ranked in seven groups: 500 largest industrials and 50 largest retail corporations (ranked by sales); 50 largest commercial banks, 50

largest life insurance companies, and 50 largest utilities (ranked by assets); 50 largest transportation companies (ranked by operating revenues); and 47 other large firms not readily classed within the previous groups (*Fortune*, May, 1970). Investment banks and privately held firms are not included on the list, and it is undoubtedly further flawed by the omission of still other firms. Nonetheless, the list is reasonably complete and most large American firms are included.

The identities of the 8,623 directors of the 797 corporations were compiled by Michael Schwartz and Peter Mariolis from standard sources (primarily Standard and Poor's *Register of Corporations, Directors, and Executives*). Interlocking directors are defined as those individuals who hold two or more directorships among the 797 firms. Many of the directors were also directors of smaller companies not appearing on the *Fortune* list, and this definition obviously undercounts the number of companies with which the directors are connected. Since our analysis will revolve around internal comparisons of the directors, however, this limitation will not seriously affect the results, though the precise details would probably differ if based on a complete list of all major U.S. firms and their directors.

Two or more directorships of the top 797 firms were held by 1,570 individuals; 61.1% serve on two boards, 21.5% serve on three, and 17.4% hold four or more directorships (one person held 11 positions, the maximum observed). For comparative purposes, an additional sample of 433 directors affiliated with only a single firm were selected randomly from the remaining list of single directors of the 797 corporations (a one-in-twenty sample).

Information on the role of the directors in institutional governance was obtained from three sources. Standard biographical data on 58% of the directors was obtained from the 1976-77 edition of *Who's Who in America*. Information on the service of the directors on federal government advisory committees was obtained from a complete listing of membership for 1976 prepared by a U.S. Senate subcommittee. This committee compiled the names of more than 23,000 individuals who served

on all 1,159 federal advisory committees, commissions, boards, councils and other panels in existence on the last day of 1976. Among the advisory committees included are the National Industrial Energy Council of the Commerce Department, the Defense Industry Advisory Group for Europe of the Defense Department, and the National Advisory Committee on Banking Policies and Practices of the Treasury Department. But also included are committees with more modest purviews, such as the Commerce Department's Advisory Committee on Fire Training and the Defense Department's Advisory Group on Utilization of Gravimetric Data (U.S. Senate Committee on Government Affairs, 1977). Finally, information on the involvement of the directors in a set of exclusive social clubs and major business policy associations were obtained from lists compiled by Phillip Bonacich and G. William Domhoff (1977). They obtained membership lists for 20 prominent metropolitan social clubs and sixteen major business policy organizations from the period between 1965 and 1971. Links, Pacific Union, and Metropolitan appear among the clubs included; the Committee for Economic Development, Council on Foreign Relations, Business Council, the Conference Board, and the Business Roundtable are among the business policy groups.²

² The data on clubs and business associations originally were organized to permit interorganizational network analysis (as reported in Bonacich and Domhoff, 1977), and only the names of those people who were members of at least two of these organizations were available for the present analysis. Not all of the clubs and associations examined by Bonacich and Domhoff included at least some of our directors on their membership rosters. The business policy associations and exclusive social clubs that did count at least one of our directors among their numbers (and each of these directors must have been a member of at least two of the organizations) are as follows; the number of directors affiliated with each is identified in the parentheses:

Advertising Council (13);
American Assembly (4);
Brookings Institution (7);
Business Council (52);
Business Roundtable (11);
Committee for Economic Development (35);
Conference Board (10);
Council on Foreign Relations (45);

The primary measure of inner group centrality for the 2,003 corporate directors studied here is the number of directorships each held in the top 797 firms in 1969. Though as many as 11 directorships were managed by one individual, the number of people holding multiple directorships is a sharply diminishing function of the number of directorships maintained, especially after the level of four directorships is reached. To ensure adequate numbers for reliable analysis, those with four or more directorships are classed together, and the directors are then divided into four groups arranged along the axis of inner group centrality, ranging from one seat on a corporate board to four or more positions.

The occupational profile and age of the four director groups are quite similar. The director's occupational position in 1969 (obtained from *Who's Who*) is considered here in three categories: executive of one of the top 797 firms; executive of other corporations; and all other occupations.³

Farm Foundation (1);
Foundation for American Agriculture (2);
National Association of Manufacturers (5);
National Planning Association (1);
Arlington Club, Portland, Oregon (1);
Bohemian Club, San Francisco (9);
Boston Club, New Orleans (1);
California Club, Los Angeles (4);
Century Association, New York (8);
Chevy Chase Club, Chevy Chase, Maryland (11);
Chicago Club, Chicago (15);
Detroit Club, Detroit (2);
Duquense Club, Pittsburgh (1);
Federal City, Washington, D.C. (6);
Harmonie Club, New York (1);
Links Club, New York (37);
Metropolitan, Washington, D.C. (46);
Pacific Union Club, San Francisco (26);
Piedmont Driving Club, Atlanta (1);
Somerset Club, Boston (2).

The requirement that each of our directors appear on the membership rosters of at least two of the organizations results, of course, in a sharp underestimate of the complete membership of the directors, since those with only a single membership are not counted. In this paper, membership in a given number of business policy associations refers to the number within the present data set, not the true number of memberships, which, in an unknown number of cases, will be one larger than the number reported here.

³ A director was considered to be an executive of a firm if he or she listed his or her primary position with the firm as any of the following: chairman of the board, vice-chairman of the board, president, chief

Table 1. Percentage of Directors Who Are Business Executives, and Mean Age of Directors in 1969, by Number of Directorships Held by Directors

Number of directorships held by director	Executive position ^a				Mean age (years)	(No. of cases)
	Top firm ^b	Other firm	Any firm	(No. of cases)		
One	46.8%	31.2	78.0	(160)	56.1	(154)
Two	46.5%	32.1	78.6	(565)	57.5	(551)
Three	47.9%	29.1	77.0	(240)	57.7	(229)
Four or more	56.5%	23.5	80.0	(195)	58.7	(186)
All directors	48.5%	29.9	78.4	(1,160)	57.5	(1,120)

^a See fn. 3 for definition of executive position.

^b Top firms consist of the 797 largest corporations from which the directors are drawn. Other firms consist of all other corporations. Any firms include both top and other corporations.

The occupational distribution of the directors, broken down by the number of directorships held, is displayed in Table 1. It is seen that, regardless of the number of directorships held, approximately half of the directors are also executives of a top firm; the percentages range from 47 for *single directors* to 57 for *multiple directors* (those with four or more directorships). More than three-quarters of all four groups are executives with either a top or other corporation (the percentages vary from 77 for the triple directors to 80 for the multiple directors). Thus, inner group centrality is unrelated to whether a director is also a corporate executive, though there is a modest tendency for higher centrality to be associated with a position among the top firms. Inner group centrality also demonstrates virtually no relationship to director age; the overall average is 57.5 years in 1969, and the average for each of the four groups deviates by less than 1.5 years from this overall mean.

In interpreting the results that follow, it should be cautioned that parts of the analysis are based on only the 1,160 directors for whom *Who's Who* information is available. Comparison of these directors with the 843 who are not listed in this biographical directory reveals that the listed directors are more prominent. For instance, multiple directors more frequently appear in *Who's Who* than do single directors (71 vs. 37%); directors who are members of two or more business

policy associations appear more often than those who are members of no associations (81 vs. 55%); and directors who are members of two or more exclusive social clubs are more frequently listed than those who are affiliated with no clubs (68 vs. 55%). Thus, analyses based on the *Who's Who* directors are of a more prominent sector of the business elite than are analyses based on all directors.

Three areas of institutional governance are considered. First, involvement of the corporate directors as trustees, directors, or governors of eight types of nongovernment, nonprofit institutions is examined. Then, we turn to the role of the directors as advisors to local and federal government agencies. Finally, the directors' involvement in business policy associations is considered.

PARTICIPATION IN THE GOVERNANCE OF NONGOVERNMENTAL, NONPROFIT INSTITUTIONS

Seven types of nongovernment, nonprofit organizations are distinguished: (1) regional, community, or economic development organizations; (2) cultural organizations (e.g., art museums, symphony orchestras); (3) research and scientific organizations (e.g., research institutes); (4) philanthropic foundations; (5) colleges and universities; (6) health-related organizations (primarily hospitals); (7) charitable organizations (e.g., The United Way). A corporate director is considered to be involved in the governance of these organizations if he or she indicated that he or she was a trustee, director, governor, or, in the case of economic development organizations, a member.

executive officer, chief operating officer, executive vice-president, senior vice-president, secretary, treasurer, general counsel, vice-president, owner, or chairman of the executive committee of the board.

The percentages of the corporate directors who participate in the governance of at least one organization in each of the seven areas appear in Table 2. The overall level of participation ranges widely by type of organization, varying from 10% for economic development organizations to 50% for colleges and universities (explanation for the considerable interinstitutional variation in overall participation rates would be a useful undertaking but is beyond the scope of the present paper). As expected, the participation rate within an institutional sector varies by inner group centrality, with single directors typically displaying the lowest rate of involvement, multiple directors evidencing the highest rate, and double and triple directors showing intermediate levels. For economic development organizations, for instance, the rates range from 6% for single directors to 10, 9, and 15%, respectively, for double, triple, and multiple directors. The ratio of the multiple director participation rate to that of single directors is 2.44 for economic development organizations, the highest observed, and only 1.14 for charitable organizations, the lowest observed. Multiple directors are more involved than single directors in all areas, though for several areas the differences are very small. For other areas, however, most notably economic development, cultural, and research and scientific organizations, the differences are pronounced.

PARTICIPATION IN GOVERNMENT ADVISORY BODIES

The second area of institutional governance, participation in government advisory

bodies, is assessed in several ways. Pre-1976 service on a federal advisory committee was identified using the director's *Who's Who* biography. This source is problematic, however, since the year of the advisory service was frequently not reported and some of the service, though probably only a fraction, was likely to have antedated the directors' election to their corporate board(s). Accordingly, the director's service on federal advisory committees during 1976 was also identified, using the U.S. Senate subcommittee compilation. Finally, advisory work with local and state government units was assessed using *Who's Who* information.

As shown in Table 3, 17% of the corporate directors report at least some pre-1976 experience as advisors to the federal government; 6% were serving on federal advisory committees in 1976, and 22% indicate that they had served as an advisor to state or local government agencies at some time. The federal agencies most frequently the recipients of the directors' advice were, not surprisingly, the Departments of Commerce, Defense, Interior, and State; presidential panels and special commissions were also frequented by the directors.

A positive association between inner group centrality and participation in governance is, once again, observed. The percentage of the directors with pre-1976 federal advisory experience varied from 14 of the single directors to 22, 23, and 31, respectively, of the double, triple, and multiple directors. Similarly, the percentages with federal service in 1976 range from 3 for single directors to 5, 9, and 11 for the successively more central groups of directors. The differentiation of the ad-

Table 3. Percentage of Directors Serving on Advisory Bodies with Government Agencies

Number of directorships held by director	Federal government				State or local government	
	Pre-1976		1976		%	(N)
	%	(N)	%	(N)		
One	14.4	(160)	3.2	(433)	15.0	(160)
Two	22.3	(565)	5.4	(959)	21.9	(565)
Three	22.5	(240)	9.2	(338)	24.2	(240)
Four or more	30.8	(195)	11.0	(273)	22.6	(195)
All directors	16.8	(1,160)	6.3	(2,003)	21.6	(1,160)
Ratio of mult. direct. % to single direct. %	2.14		3.43		1.51	

visory experience by centrality is also replicated on the state and local level, though the disparities are far less marked. Here the participation rate varies from 15% of the single directors to 22, 24, and 23% of the double, triple, and multiple directors. The ratio of the participation rate for multiple directors to that of single directors is 2.14 for pre-1976 federal advisory service, 3.43 for 1976 federal advisory committees, and 1.51 for state and local government service. Thus, the association between inner group centrality and institutional governance observed for several types of nongovernmental institutions is also observed here for federal and local government advisory service.

PARTICIPATION IN MAJOR BUSINESS POLICY ASSOCIATIONS

The final area of institutional governance is participation in the work of major business policy associations. Business trade associations abound, of course, and most are organized to defend the interests of a particular type of industry, such as oil or steel, or to promote business interests in a local region. Yet a number have been established to provide a forum for the discussion and articulation of policies that affect most major companies, regardless of sector or region. These associations usually draw their members from the top ranks of a broad range of corporations scattered throughout the country; in some cases their rosters also include academics, attorneys, and other professionals actively concerned with the business world. Case studies of several major business associations suggest that they play an important role in establishing a common business position on contemporary issues,

especially in the area of public policy (e.g., see Eakins, 1966; Domhoff, 1970; 1975; Shoup, 1975; Hirsch, 1975; Fournier, 1976; Bonacich and Domhoff, 1977). Since the associations serve as a significant interface between business and government, direct participation in their affairs can have an important impact on the nature of public policies collectively promoted or opposed by business. The multifirm connections of inner group members should make them particularly valuable and forceful contributors to such organizations, and it is expected, therefore, that inner group centrality should be strongly associated with participation in the affairs of these business policy groups.

Rates of participation in the Council on Foreign Relations, Committee for Economic Development, Business Council (all closely identified with major corporations) and nine other associations are shown in Table 4. Overall, 12% of the directors participate in the affairs of at least one association, but when the rates are broken down by number of directorships, pronounced variations from this average become evident. The proportion of single directors active in one association is less than 1%; the percentages for

Table 4. Percentage of Directors Who Are Members of 12 Major Business Policy Associations

Number of directorships held by director	Member of one assoc.	Member of two or more assoc.	(No. of cases)
One	0.2%	0.2	(433)
Two	5.9	3.6	(959)
Three	11.2	6.8	(338)
Four or more	19.4	13.6	(273)
All directors	7.4	4.8	(2,003)

double, triple, and multiple directors are 6, 11, and 19. Similarly, the rates for those involved in at least two associations for the four directorship levels are, respectively, less than 1, 4, 7, and 14%. Less than 1% of the single directors participate in even a single association, while 33% of the multiple directors are active in one or more associations. It is in this area of governance that the greatest participation rate disparities as function of inner group centrality are observed.

CORPORATE RESOURCES AND SOCIAL NETWORKS

Earlier it was argued that an observed association between inner group centrality and participation in governance would be expected for at least several reasons. First, by virtue of oversight responsibilities for several major corporations, inner group members are in a position to mobilize greater resources on behalf of favored policies and institutions than are single directors. From the standpoint of the institution seeking business participation, inner group members can provide greater support for, and exert more influence on behalf of, the institution than can businesspeople associated with only a single firm. Second, participation in the boards of directors of several firms helps generate informal contacts with other multiple directors, and a national social network of multiple directors is likely to form.⁴ Again, from the standpoint of the institution seeking corporate representatives, members of this network can provide better social contacts and a broader understanding of business inter-

ests than would outsiders. Thus, the multiple directors' greater access to corporate resources and involvement in transcorporate, national social circles of top business leaders make them more attractive candidates for institutional governance than are other businesspeople. Moreover, the multiple directors' better corporate and network connections should give them a competitive edge over other directors when seeking to participate in the affairs of other institutions. They would be able to mobilize more firms and more business leaders to back their candidacy than would other, less connected and less visible corporate directors.

Still other factors were previously argued to contribute to the greater governance participation rate of multiple directors. But in any case, if corporate resource and social network factors do play a major role as expected, several observable patterns are anticipated. First, among directors with a fixed number of directorships, those serving on the boards of larger corporations are in a position to mobilize greater resources than are those associated with a similar number of smaller companies. Thus, holding the number of directorships constant, we should expect to see a larger average corporation size among those participating in institutional governance than among non-participants. Second, multiple directors are expected to be more heavily engaged in social networks among their own kind than single directors, and involvement in these networks should, in turn, independently enhance the directors' participation rates. Though our data do not permit detailed assessment of these hypotheses, at least elements can be checked with the information available.

A. Corporate Resources

While corporate size is a reasonably good measure of corporate resources, the size of the 797 firms is measured within the seven distinct sectors utilizing varying criteria (sales, assets, and operating revenue). The resources of all firms cannot, therefore, be readily assessed according to sales or any other single dimension of size. Of several alternatives considered,

⁴ Other points of contact among the multiple directors surely contribute as well to the formation of this network. Limited available evidence suggests that inner group members are more likely to be descendants of business elite families than are other members of the business elite. And other studies indicate that this social origin is often associated with a set of opportunities favorable to the formation of enduring social contacts among those of similar heritage: invitations to elite-sponsored social events, visits to exclusive vacation communities, attendance at elite preparatory schools and universities, and induction into exclusive societies and social clubs (Mills, 1956; Baltzell, 1964; Lundberg, 1968; Domhoff, 1970; Useem and Miller, 1975).

the following procedure for establishing a common size dimension offered the most suitable approach (the alternatives yielded results little different from those reported here). The rank position of the corporations within each sector is used as a base for a general resource index. The 500 industrials were ranked from one to 500 according to firm sales. The sales figures for 1969 ranged from slightly more than \$100 million for those ranked near 500 to between \$10 and \$20 billion for those near the top (General Motors is ranked one). The sales rank of these firms is similar to a logarithmic transformation of their dollar sales figures. The rank position of the fifty firms in each of the other six sectors, where rank position is established according to sales, assets, or operating revenues (depending on the sector), is simply set as equivalent to the rank of the largest 50 industrials. The commercial bank and insurance company with greatest assets, for instance, are both assigned a rank of one (in effect equating a directorship with either of them to a di-

rectorship with General Motors), while the 50th largest bank and insurance company are each assigned a rank of 50. The average rank of the firms of the directors is then calculated separately for double, triple, and quadruple directors (too few directors with more than four directorships were available for separate reliable analysis). Finally, the average of these averages is obtained for groups of directors who are involved and uninvolved in seven areas of governance that previously evidenced strong associations with inner group centrality.

The average ranks are shown in Table 5. The mean rank of the firms of double directors who were not involved in any economic development organization stood at 128, while the mean rank of those who did participate was 98, for an average difference of 30 rank positions. Similarly, among those with three directorships, the average rank of the corporations of economic development participants was 19 positions larger than the rank of the corporations of nonparticipants; the corre-

^a Under the *No* column appears the mean rank of the firms of directors who were not involved in the given area of governance; beneath the *Yes* column appears the mean rank of the firms of directors who were involved with at least one organization in the given area of governance; the *Diff.* column displays the difference between these two figures.

sponding rank difference for those with four directorships was 13. Comparable patterns are observed in the six other areas of governance examined: cultural organization governance, research or scientific organization governance, service as a federal advisor both before and during 1976, service as a state or local government advisor, and involvement in business policy associations. Of the 21 calculated differences for the seven areas of governance, only two were contrary to the expected direction (among double directors for research organization governance and quadruple directors for pre-1976 federal government advisory work). The median observed difference is 20 rank positions, which translates for the industrials into a sales difference of approximately \$190 million on a base of roughly \$1.2 billion. Participants were typically associated with firms approximately one-sixth again as large as the firms of nonparticipants. The gaps are not of great magnitude, but they are consistently present in nearly all seven areas of institutional governance. As expected by the resource hypothesis, then, the likelihood that directors with a fixed number of directorships are involved in governance is a positive function of the size of the corporations with which they are associated.⁵

The validity of the resource explanation is further suggested by the consistency of the present findings with those reported in two other studies in radically different settings. In a study of the 86 largest Dutch corporations in 1969, Mokken and Stokman (1978) find that the directors of the largest firms were substantially more likely to be involved in the affairs of government in the Netherlands than were the directors of smaller corporations. Simi-

larly, in an investigation of the local governance activities of the directors of local banks in St. Louis in 1975, Ratcliff et al. (1979) discover that bank size is strongly correlated with director participation in the governance of local charitable organizations, cultural organizations, and a business policy association.

B. Social Networks

The social network hypothesis suggested that the observed association between inner group centrality and participation in institutional governance is also partly the result of greater involvement of multiple directors, compared with single directors, in social circles among their own kind. Network participation cannot be directly assessed, but membership in the business policy associations does provide one indirect indicator of network involvement. Activity with such associations bring members into personal contact with the officers and directors of numerous large corporations located throughout the economy and the country. The resulting networks of acquaintanceship provide their members with an assessment of one another's leadership capacities and views on matters of public policy. Along with the ties of personal obligation which accompany the formation of social networks, these elements enable members more forcefully and effectively to promote each other for openings in the governing bodies of other institutions.

We have already seen that the number of corporate directorships and rate of participation in business policy associations are related, implying, if the previous assumptions are correct, that multiple directors are more active than other directors in the social networks that should bring them into prominence. To examine whether business policy association participation is in turn related to participation in other areas of institutional governance, we examine these participation rates as a function of business group membership. Table 6 displays the percentages of the directors who were active in six areas of governance, broken down into those who were members in no, one, and two or more business groups. The percentages

⁵ Since most (77%) of those with two to four directorships held these with firms in at least two sectors, the present analysis could not be undertaken separately within each of the seven sectors (a procedure that would have negated the need for the assumption that firms of similar rank in different sectors could be considered to represent equivalent resources). However, a sufficient number of the two-board directors with both positions located in the industrial sector was available to permit analysis limited to this group alone (N=170). The results of this more limited analysis are generally consistent with those reported above for the full analysis.

Table 6. Percentage of Directors Who Participate in Six Areas of Institutional Governance, by Number of Memberships in Major Business Policy Associations

Number of business assoc. memberships	Economic develop. organ. ^a	Cultural organ.	Research or sci. organ.	Federal advisor pre-1976	Federal advisor 1976	State or loc. gov. advisor
Zero	8.2%	18.5%	15.2%	19.6%	5.5%	21.9%
One	16.5	30.4	19.1	33.0	10.7	19.1
Two or more	20.5	29.5	30.8	44.9	14.6	20.5
Ratio of two assoc. % to no assoc. %	2.50	1.59	2.03	2.29	2.65	0.94

^a The number of cases on which the percentages are based is 967 for those with no business association memberships, 115 for those with one membership, and 78 for those with two or more memberships, except in the case of the federal-advisor-1976 variable, for which the numbers of cases are 1,758, 149, and 96, respectively.

show the expected pattern for all areas except state or local government advisory service. Of the directors without business association membership, only 8%, for instance, were involved with economic development organizations, whereas the percentages for those with one and at least two associations are 17 and 21, respectively. The ratio of the participation rates of those with two or more business association memberships to those with none is 2.50 for economic development organizations; 1.59 for cultural organizations; 2.03 for research or scientific organizations; 2.29 for pre-1976 federal advisory service; and 2.65 for 1976 federal advisory work. The ratio for state or local government advisory service, however, is less than one.

It is evident, then, that number of directorships is strongly associated with participation in business policy organizations, and that this participation is strongly associated with involvement in other areas of institutional governance. If indeed network involvement, as indexed by business association membership, is a factor in the multiple directors' preferential selection for institutional governance, the degree of association between the number of directorships and institutional governance should be reduced when business association membership is held constant. This possibility can be examined with multivariate table analysis, but a more compact form of presenting the results can be achieved using correlational analysis, and this will be employed here. The variables also are made more compact for the analysis, as follows: the economic development, cultural, and re-

search or scientific organization variables, in dichotomized form, are summed to form a *civic governance* variable (ranging from zero, for no involvements, to three, for participation in all three areas); the two federal government advisory variables, also in dichotomized form, are summed to form a *government advisor* scale (ranging from zero, for no service, to two, representing both pre-1976 and 1976 advisory service); *directorships* consists of the number of corporate directorships held (with more than four scored as four); and *business association* represents the number of business policy group memberships (with more than two coded as two). Because state or local government advisory service already has been found to be unrelated to business association membership, it is not included in the analysis.

The relevant simple correlations among these variables are displayed in Table 7. The correlation of directorships with business association is .26, with civic governance it is .14, and with government advisor it is .12. These figures are consistent with results obtained from the previous bivariate table analyses. Business association also is seen to correlate with the two governance dimensions (.17 and .18). If business association does, indeed, account for a substantial fraction of the relationship between directorships and the two governance dimensions, the correlation between directorships and each governance dimension should be reduced when business association is introduced as the control variable in a partial correlation. This does occur, as shown in Table 7. The partial correlations of directorships with civic governance and government

Table 7. Simple and Partial Correlation of Civic Governance and Government Advisor with Number of Directorships, Net of Business Association Membership

Variable	Mean ^a	Std. dev.	Correlation with no. of directorships	Correlation with bus. assoc. mem.	Partial correlation with directorships, net of bus. assoc. memberships
Directorships	2.405	.924			
Business association	.234	.560	.262		
Civic governance	.469	.678	.144	.170	.105
Government advisor	.318	.548	.120	.182	.076

^a All figures are based on 1,160 cases.

advisor, net of business association, are .11 and .08, respectively; these represent 73 and 65% of the simple correlations.

It appears, therefore, that social networks, as indexed by involvement in business policy association affairs, do facilitate the involvement of multiple directors in the governance of other institutions. The business policy associations would appear not only to help develop common business positions on matters of public debate, but also to provide a screening mechanism for selecting businesspeople to help oversee the affairs of other institutions. Inner group members disproportionately participate in such oversight in part because they disproportionately participate in business policy associations and the social networks they generate. The business policy associations examined here, all national in orientation and scope, do not appear to be responsible for screening members for state or local government advisory work. It may be that other, more locally oriented business groups, are responsible for this process at the local government level.

CONCLUSION

The evidence presented here indicates that, in regard to the placement of corporate directors in positions of governance over nonbusiness institutions, the capitalist class is differentiated, as expected, along an axis of inner group centrality. In three distinct areas of governance, variant participation rates were observed as a function of position on the inner group axis. Multiple directors were more likely to be involved than single directors in the governance of several types

of nonprofit private organizations (especially economic development, cultural, and research or scientific organizations), as advisors to local, state and national government agencies, and as members of major business policy associations. The participation rates of multiple directors frequently were observed to be more than twice those of single directors, with double and triple directors usually exhibiting intermediate rates. The consistency of these patterns across many areas of institutional governance provides tentative confirmation for the thesis that inner group members are generally more likely to serve as business representatives in nonbusiness governing bodies and positions than are other business people.

The disproportionate involvement of inner group members in institutional governance was expected, in part, because of their greater capacity to mobilize corporate resources and because of the likelihood that they would be more involved in a national, transcorporate social network of corporate directors. It was anticipated that these factors would result in inner group members more often being promoted for institutional governance positions by other members of the business elite, and in inner group members being more desirable business representatives from the standpoint of the recipient institution. The limited evidence considered here is consistent with this line of reasoning. Indexing corporate resources by the average rank size of the firms with which the directors were connected, and using membership in major business policy associations as an index of social network involvement, we found that both hypothesized factors did appear to be responsi-

ble, in part, for the overrepresentation of inner group members.

Several limitations on the validity and generalizability of these results, however, should be noted. First, a select set of corporate directors was studied, and it is possible, though improbable in my opinion, that the analysis of a set of directors drawn from a larger, more comprehensive list of companies would yield different conclusions. Second, more potentially problematic is the quality of the indicators employed in the study. The difficulty of acquiring precise, detailed information on the characteristics of a large set of corporate directors, their firms, and their participation in the governance of a variety of institutions necessitated reliance on available but often imprecise indicators for the variables of interest. No direct measure of social network participation for the more than 2,000 directors could be developed, for instance, leading to the use of an acceptable though clearly less than ideal proxy measure, business association membership. Our measures offer only a first approximation to the empirical relations among the variables of concern. It is expected, however, that more exact indicators would yield results generally consistent with those reported here while perhaps differing substantially in detail. For some variables, radically different empirical approaches may be required to acquire the direct and precise information needed. Perrucci and Pilisuk's (1970) method of obtaining social network information through personal interviews with multiple directors in a single community might be extended to the national level, though cost may prohibit the approach of more than a small subsample of the directors studied here.

A third limitation relates to what was not examined in this paper. As Alford and Friedland (1975) have argued, power cannot necessarily be equated with participation, although there is usually a strong relationship between these analytically separable dimensions. Thus, it should be cautioned that the overrepresentation of inner group members in governance does not automatically imply that they are decisively shaping the policies of the subject

institutions. Empirical studies of boards of directors and government advisors generally show that they do have an important impact on the institution's future (e.g., Wilensky and Lebeaux, 1958; Paltridge et al., 1973; Primack and von Hippel, 1974). If the results of such studies can be generalized, it may be speculated that the participating corporate executives are indeed exercising an important voice in the affairs of the institutions considered here. But the exact strength of their voice can only be a matter of theoretical supposition at this time, and further study obviously is required if we are to specify the amount of power that accompanies the participation.

A final limitation relates to a distinction between the exercise of power and the content of policies promoted. As Charters (1953) and Poulantzas (1969) have argued in connection with the role of business people on school boards and in top government positions, business participation does not necessarily imply that the interests of capital in general, or even the business person's own firm, are advocated. Even if the corporate directors in the present study do exercise considerable power over the institutions in whose governance they participate, it remains to be demonstrated that their power is exercised on behalf of anything but the best interests of the subject institution. It can be reasoned that inner group members are more likely than other members of the business elite to advocate the general concerns of business, and that both groups are likely to take more pro-business stands than do nonbusiness people involved in institutional governance. And while these arguments are relatively persuasive and evidence from other studies can be cited to bolster them, it remains to be shown that the corporate directors studied here do forcefully represent the interests of their class, or at least a major fraction of it, when they participate in the governance of other institutions. The thesis is plausible, yet unproven. The present paper, then, has explored only one part of the business-institutional governance relationship, and speculation about the operations of the other parts awaits verification.

But even short of verification of the other elements of the business-institutional governance relationship, the present evidence points toward the need for a revision in our thinking about the internal social organization of the American capitalist class. Business is differentiated along an axis of inner group centrality, and this element of internal organization appears to have a major bearing on how business is structured to express and represent its interests in places where other institutions are making decisions that can vitally affect business.

The political salience of the inner group axis stems in all likelihood, from several elements in the relationships among major corporations, their managers, and primary owners. Firms and those responsible for them are, of course, sharply divided by interfirm and intersectoral competition and rivalries. And the divergent economic circumstances faced by those overseeing firms operating in different environments add further division, especially when owners and managers specify the policies they would urge upon government agencies, cultural organizations, universities, and other institutions. Without suitable means for reconciling these antagonisms and identifying the common concerns of all business, political leadership for the capitalist class is unlikely to emerge. The divisive tendencies may then result in public policies which benefit some sectors or firms but do little to advance the general welfare of most major corporations and the class as a whole.

Though not self-consciously designed to solve these problems, several formal and informal relationships among corporations and their owners and managers nonetheless are likely to contribute toward their solution. Among these relationships are a network of kinship and acquaintanceship among corporate managers and owners spanning many corporations (Whitley, 1973); the diversification of institutional and family corporate holdings (Lundberg, 1968); the integrative role of commercial banks and other financial institutions (Kotz, 1978); social associations transcending firm, sector, and region, such as business policy organizations and exclu-

sive metropolitan social clubs (Baltzell, 1964); and the interlocking directorate studied here. The social forces behind the formation of each of these integrative relationships require separate analysis, but, whatever their origins, the consequences are likely to include a set of transcorporate networks that draw together the otherwise disparate units of the business elite. These disparate units include not only individuals but also specialized elite networks organized within metropolitan areas and within business sectors. Available research indicates that these contexts generate their own, specialized inner circles (Perrucci and Pilisuk, 1970; Ingham, 1978; Ratcliff et al., 1979), and it is probable that these and other types of localized networks provide many of the constitutive elements for the national, intercorporate networks that help to unite the entire class.

Concentrating on only a single strand of these various integrative networks, the present analysis tentatively confirms the thesis that this strand is a source of the "leading organizers of [the] system of class-wide property" (Zeitlin, 1976: 901). Those most central to the interlocking directorate are observed to be those most often involved in representing business interests, presumably shorn of many of their more parochial elements, to other institutions. A more precise identification of the "leading organizers" of the capitalist class than that achieved here would be possible if evidence were obtained on the other relationships contributing to the integration of the class and its firms. Unfortunately, adequate data on kinship, ownership, and other intercorporate networks is far less accessible, for the present at least, than is information on the network of corporate directorships. Were such information to become accessible, it can be speculated that those most central to these various networks are also those most active politically both within and outside the corporate community. Combined with the results of the present analysis, such findings would help to establish a more general thesis that the American capitalist class is characterized by a substantial degree of centralized

internal social organization, and the centralization, however faulty it may be in specific instances, provides a means for the entire class to distill and promote its most general class-wide interests.

As a result, the government and other institutions are not simply presented with a set of unaggregated demands when businesspeople enter their policy-making circles. Rather, the businesspeople who most often serve already represent a degree of reconciliation of the conflicting and contradictory interests dividing the capitalist class. The corporate community itself, then, appears at least partially capable of identifying its class-wide interests. While the state and other institutions may still play a critical role in "the liberation" of general interests from the "fragmented, stubborn, and shortsighted empirical interests of single capital units" (Offe, 1973: 111), the class may achieve a degree of prior interest "liberation" on its own.

This general thesis must be treated for the moment, however, more as a guide for further inquiry than an accepted description of the organizational coherence of the American capitalist class. Moreover, whatever the extent of class centralization eventually identified, there is reason to believe that it may be less pronounced in the U.S. than in Britain, France, and other advanced capitalist democracies where the business elite's geographic concentration is far greater, elite institutions such as universities and social clubs are more exclusive, and the level of organization and militancy of labor and socialist movements is much stronger.

POLITICAL DEMOCRACY AND THE TIMING OF DEVELOPMENT*

KENNETH A. BOLLEN

Brown University

American Sociological Review 1979, Vol. 44 (August):572-587

This research explores the relationship between development timing and political democracy. A number of social scientists have argued that the conditions favoring political democracy have deteriorated over time so that the late developing countries are less likely to be democratic than are the early developers. Another perspective suggests that with the worldwide diffusion of the democratic ideology there is a great deal of pressure for the later developers to adopt democratic forms of government. For a large sample of countries, this analysis reveals no significant relationship between the timing of development and the level of political democracy. However, when more specific characteristics of development timing are explored, some significant effects are found. In particular support is found for the hypotheses that the greater the extent to which a culture is Protestant-based, the greater the level of political democracy; and the greater the state's control of the economy, the lower the level of democracy. In a panel analysis, changes in political democracy are found to be negatively related to the state's economic control but not significantly related to Protestantism. In all of the regressions the level of development has a more significant direct effect than the various timing measures.

The positive relationship between socioeconomic development and political democracy has been the subject of considerable empirical research (e.g., Lerner, 1958; Lipset, 1959; Cutright, 1963; Cutright and Wiley, 1969; Jackman, 1973). In more recent empirical studies the relation-

ship between political democracy and income inequality has been examined and debated (Jackman, 1974; 1975; Hewitt, 1977; Robinson and Quinlin, 1977; Stack, 1978; Robinson, 1978). In contrast to this empirical research a number of theoretical works have emphasized the effects on political democracy of the historical period when a country begins to develop (e.g., de Schweinitz, 1964; Moore, 1966). These latter works have concluded that the social, economic, and political conditions which existed for the earlier developers were far more conducive to democ-

racy than are the conditions facing the late developers. As a result, the early developers are viewed as more likely to be democratic than are the more recent developers.

Many of the countries which are at the highest levels of economic development are also the nations which began to develop in the earliest historical periods. This raises the question of whether it is the historical *timing* or the *level* of development that is the primary determinant of political democracy. If the historical period of development has the dominant influence, the chances for political democracy would not improve with socioeconomic advances. The characteristics of the time at which a society began its development would fix the form of its political system. In contrast, if developmental factors are more important, the level of political democracy would not be fixed but would be associated with socioeconomic changes. This paper presents and tests several major hypotheses on the effects of the timing of development on democracy while controlling for the level of development.

EARLY AND LATE DEVELOPMENT EFFECTS

The time in world history when a country begins to develop will affect its social, economic and political systems (see, e.g., Black, 1966; Levy, 1966; Seers and Joy, 1970). Britain, the first economy to "take-off" into rapid economic growth, altered the path of development for all the countries that were to follow it. It established a model of economic development that influenced France, Belgium, America and numerous other countries. As the number of successful economies grew, the pool of potential models for the industrial development of other countries grew. At the same time the relevance of the traditional development models became questionable. Part of the reason for the irrelevance is that the first developers were largely from a similar western cultural heritage. In contrast, the later developers represent a more heterogeneous set of sociocultural systems, some of which are not easily malleable to the transformations required to begin and maintain economic

development. It is an open question whether democratic forms of government are consistent with the diverse sociocultural systems of these countries.

In addition many of the late modernizers face greater strains in their societies than were present in the first developers. Part of this strain is caused by what is often called *demonstration effects*. That is, the latecomers are well aware of what goods economic development can bring to their society and at the same time they are aware of their own economic backwardness. Rather than having a population willing to save and invest for an unknown future there is a great deal of pressure in the late developers for immediate consumption and social welfare as is found in more mature economies. A political democracy allows these rising and often competing demands to impinge upon the political system while the developing country's economic system is not advanced enough to satisfy the demands. These pressures may lead to the collapse of democratic regimes and give rise to a more authoritarian government which may or may not be better able to meet the demands but will be more successful in suppressing the demands.

Further strain is placed on the developing societies as a result of their rapid increases in population. The rapid diffusion of public health programs and inexpensive "death-control" technology to many of the Third World nations, has led to tremendous drops in mortality (Davis, 1956; Gray, 1974). The rapid declines in mortality have not been accompanied by proportional drops in fertility and the result has been unprecedented increases in population. The population increases have put more pressure on the resources of the societies to feed, clothe and house a substantial number of new individuals who will not contribute to the work force for years to come. Emigration, which might relieve some of the population pressure, is made nearly impossible by quotas and immigration restrictions that are found in both developed and developing countries (de Schweinitz, 1964).

The population problem and the other strains associated with late development are believed to make it difficult for a

democratic form of government to be effective in developing nations (de Schweinitz, 1964; Moore, 1966). A democratic form of government is seen as a luxury that cannot be afforded by a nation struggling to overcome poverty and starvation. In addition the birth control policies, economic and social changes that are considered essential to development are viewed as nearly impossible to achieve within a democratic framework. Instead, an authoritarian government with a concentrated distribution of political power is seen as a likely and necessary response to the tensions of late development (Heilbroner, 1974). The earlier developers did not have to cope with the same strains that are faced by the latecomers. They could afford to develop with a more diffused distribution of political power.

The world system and dependency perspective on national development suggest some additional reasons why the early developers are more likely to be politically democratic than are the late developers. In this perspective the early developers such as the U.S., U.K., France, etc. are considered the "core" nations of the world system. Political democracy is viewed as a system established by the elites within the core nations to avoid massive conflict with the core nonelites (Wallerstein, 1977: 34). The ideology of political freedom and democracy spread rapidly through the early developers and made authoritarian political control give way to more subtle economic forms of control.

In contrast, the late developers are viewed as the peripheral nations in the world system. Their underdeveloped status is seen as at least partially a consequence of the development of the core nations (see, e.g., Baran, 1956; Frank, 1973; Wallerstein, 1974; Chase-Dunn, 1975). Galtung (1971), along with other dependency theorists, has emphasized the commonality of interests shared by the elites in the periphery nations and the elites in the core nations. The core nations are said to provide monetary and political rewards to those elites in the periphery nations that help advance the core elite's interests. "The power of the elites in dependent peripheral countries is backed by

their alliances with the core. . ." (Chase-Dunn, 1975:724). The political power of the elites in the late developing periphery is strengthened by the support they receive from the core, early developers. The elites in the periphery may then be better able to maintain authoritarian rule. Thus, the late developers (or periphery nations) are less likely to have democratic political systems than are the early developers (or core nations).

Based on these and other conditions of early and late development a number of authors (e.g., de Schweinitz, 1964, and Moore, 1966) have suggested the following hypothesis:

Hypothesis 1: The earlier a country begins to develop, the higher its level of political democracy.

The early developers provided not only a model of economic development (as described above) but also a model of political "development." Most of the early developers of Western Europe and North America evolved political systems that were more democratic¹ than that found in other countries. The democratic ideology which legitimizes the democratic political system has become an important component of the political culture of these nations. The ideal of "rule by the people" has moved beyond the borders of the early developers and has spread to all corners of the globe. "Participation in public affairs at the national level has widened: in one country after another the earlier dichotomy between rulers and ruled has become blurred" (Bendix, 1976:245).

The democratic ideology has been spread by books, movies, radios, and other vehicles of cultural transmission. The education of many of the Third World elites in western universities or under western systems of education also contributed to the diffusion of the belief in popular sovereignty. Ironically, the often nondemocratic colonialism of western

¹ The differences in political power between males, females, races, occupations, and educational groups are obvious reminders that the democratic ideal is far from being met in any country developed or not.

powers served to spread the democratic ideal if not the practice.

Although the spread of the democratic ideology has been worldwide, institutionalizing the ideal has proved far more difficult as is exemplified by the alteration of democratic to authoritarian governments in some Third World nations. However, the spread of the ideal has put authoritarian governments in a defensive position. A concentrated distribution of power must be justified to the masses within a country as well as to world public opinion. This will exert pressure toward more rather than less democratic forms of governments in the late developers.

The above argument suggests a second hypothesis that makes a prediction contrary to Hypothesis 1.

Hypothesis 2: Because of the diffusion of the democratic ideal over time, the later the time of development the more pressure toward adopting a democratic form of government.

In addition to these two general timing hypotheses, a number of more specific characteristics of early and late development have been hypothesized to affect political democracy. In the next two sections the effects on political democracy of a Protestant-based culture and the strength of the state are discussed.

PROTESTANT-BASED CULTURE

One specific characteristic of the early developers which has been hypothesized to facilitate the rise of democracy is the extent to which a culture is influenced by Protestantism. As argued above, the diffusion of the democratic ideology has been worldwide. However, democratic political systems have seemed to receive their greatest legitimation in Protestant-based cultural systems. Lenski and Lenski (1974:349) argue that Protestantism was largely responsible for the extensive diffusion of the democratic ideology: "Among the various factors that contributed to the rise and spread of the

new democratic ideology, Protestantism looms large. Whatever else the Reformation accomplished, it proved that established authority could be challenged and overthrown."

Schumpeter (1950) claims that Protestantism served to legitimate the democratic ideology through closely related religious beliefs. For example, the ambiguity in interpreting the will of God was resolved by seeking the will of the people. In a similar manner the values of "equality" and the importance of all individuals were legitimated by and consistent with Protestant religious beliefs (Schumpeter, 1950: 265).

The relatively democratic governments of Japan, Israel and India, among others, are sufficient to demonstrate that Protestantism is not a *necessary* condition for democracy. Rather, the role of Protestantism is that of aiding the diffusion of and legitimizing values associated with, political democracy. These arguments lead to the formulation of a third hypothesis.

Hypothesis 3: The greater the extent to which a nation's culture is Protestant-based, the higher its level of political democracy.

STATE'S ROLE IN ECONOMIC SYSTEM

The state or government's control of the economic system was relatively minor in the early developers. Instead the means to attain economic advancement were open to private, entrepreneurial experimentation. The commercial class in the early developers was able to gain a status significantly independent of the agricultural elites (Moore, 1966). The relative autonomy and freedom of the commercial class led to even greater economic growth. As Landes (1969:19) observes:

those economies grew fastest that were freest. This is not to imply that state enterprise or control is intrinsically inferior to private enterprise; simply that, given the state of knowledge in pre-industrial Europe, the private sector was in a better position to judge economic opportunity and allocate resources efficiently.

Thus, the early developers' push toward industrialization was engineered by private entrepreneurs with a minimum of state intervention.

Karl de Schweinitz (1964) argues that the advancements of the early developers generated by a relatively autonomous commercial class diminished the political power held by the traditional governing elite. The economic gains of the commercial class led to their demands and receipt of a larger share of political power. In short, the minimal role of government in the economic development of the early developers seemed favorable to the extension of democracy in the political sphere.

The close connection between political democracy and this capitalist form of development has been recognized at least since the writings of Adam Smith. The ideal of a competitive and free struggle for leadership in democracies is quite consistent with the ideal of competitive and free trading in a market economy. In the political sphere the vote may be considered analogous to the dollar as a purchasing unit that, instead of buying economic goods, is spent in the selection of the ruling elites. Schumpeter's (1950:285) quote of a successful politician illustrates this point: "What businessmen do not understand is that exactly as they are dealing in oil so I am dealing in votes."

The capitalist mode of development, which was characteristic of many of the early developers, plays a less important role in the late developers. In response to foreign economic and political penetration and/or to overcome economic stagnation, the government in many of the latecomers will often play a more active economic role than was true in the early developers (de Schweinitz, 1964; Rubinson, 1976). The state may be the only domestic institution that can accumulate the great amount of capital that is required to stimulate development. The nationalization of industries, the imposition of quotas on imports, and the creation of programs to increase native production are all examples of the enlarged role that the late developers' governments play.

According to de Schweinitz (1964:59-75) the state or government in the latecomers is also likely to play a bigger part in handling the discontent of labor

that accompanies a higher level of economic development. In the early comers labor was able to organize largely independently of the state. In the process of organization and legitimation the laborers gradually were able to attain a greater amount of political power. The late developers, however, cannot afford to have the growth processes slowed down by the demands of labor. Karl de Schweinitz argues that the state tends to incorporate the labor unions into the government so that they do not have a chance for autonomous development. The close ties of labor organization and the state weakens the impetus toward a more diffused distribution of political power. Under these conditions the political elites will be able to maintain a concentrated distribution of power. Moore (1966) also argues that the state plays a much larger role in the development of the latecomers. He hypothesizes that with the change from the bourgeois revolutions of the early developers to the "revolutions from above" and the "peasant revolutions" of the latecomers, the chances for political democracy have been greatly diminished.

These arguments suggest that if a state or government exercises a great degree of control in the economic system this will lead to a more concentrated distribution of power in the political system.

Hypothesis 4: The greater the state's control of the economic system, the lower the level of democracy in the political system.

MEASURES

A sample of 99 countries at widely varying levels of development is used for the empirical analysis. Because data for the state's control of the economic system are not available for Communist countries (except Yugoslavia) the sample omits these societies. The following measures are used to operationalize the theoretical concepts that are specified in Hypotheses 1-4.

Time of Development

The time in world history that a nation begins to develop is a rather complex con-

cept. It is not the "time" per se that is important but the combination of variables characterizing a historical period. Hypothesis 1 represents the views of some theorists that the factors characterizing the historical periods of the earlier developers favored political democracy. These favorable factors have steadily deteriorated over time so that the later the development the more obstacles to democratic development. Hypothesis 2 supports the opposite generalization; the conditions for democracy have improved, the later the time of development. When measuring the time of development it is difficult, if not impossible, to single out a particular year that unambiguously marks a starting point in a nation's development. There is also the possibility that "breakdowns of modernization" may occur (Eisenstadt, 1964). Regional differences in starting points of development within nations are also likely. For example, in the United States the East began a period of rapid growth before other regions of the country. However, there are clearly differences in the timing of development when contrasting the various nations of the world so that it is possible to derive *approximate* starting points.

For this research two measures of timing are used. The first is measured by Black (1966) as reported in Taylor and Hudson (1971). It is the approximate year at which the consolidation of modernizing leadership occurs and is the first step in the development process.

The consolidation is marked by three characteristics: (1) the assertion of the determination to modernize; (2) an effective and decisive break with the institutions of an agrarian way of life; and (3) the creation of a national state with an effective government and a reasonably stable consensus on political means and ends by the inhabitants. (Taylor and Hudson, 1972: 16)

The timing variable was scored by subtracting the starting year of development for each country from 1966.² This gives the highest score to those countries which have been developing the longest and the lowest scores to those countries recently beginning to develop.

² The year 1966 is arbitrary. Any other year could be chosen without affecting the results.

As an added check on the timing hypothesis a second measure of the timing of development is used for a smaller sample of countries. This is the approximate economic take-off date from Rostow (1961:38; 1971:55) and Collier (1975:341). Rostow (1961:39) establishes three criteria to be met for a country to attain economic take-off:

- (1) a rise in the rate of productive investment from, say, 5% or less to over 10% of national income (or net national product [NNP]);
- (2) the development of one or more substantial manufacturing sectors, with a high rate of growth;
- (3) the existence or quick emergence of a political, social and institutional framework which exploits the impulses to expansion in the modern sector and the potential external economy effects of the take-off and gives growth an on-going character. (Rostow, 1961:39)

Rostow lists take-off dates for a little over a dozen countries. This sample is too small to be reliable. Collier's (1975) economic take-off date for Latin American countries supplements Rostow's measure.

Collier (1975) measures the economic take-off date by using the physical indicator of when a country reached electric production of .10 kilowatt-hours per capita. He finds that this indicator, as well as several other physical indicators, lead to take-off dates that are close to Rostow's take-off dates for the few countries where Rostow's and Collier's (1975: 340-1) sample overlap. A combination of Rostow's and Collier's take-off dates form the second timing measure.³

Protestant-Based Culture

An indicator of how much a cultural system derives from Protestant ideas is the proportion of a nation's population that is Protestant. For most parts of the world the percentage of Protestants in a

³ To maintain comparability with the rest of the analyses, I did not use the economic take-off dates of the Communist countries of China, Cuba and Russia. In a regression not reported here these countries were used in an analysis which included a dummy variable for Communist countries. The basic results were the same as reported in Table 2—the coefficient for the economic take-off was not significantly different from zero.

nation has changed very slowly. For the African nations where there is increase in Protestantism, this data is for 1965 (Taylor and Hudson, 1971).

State's Control of Economic System

One indicator of the state's control of the economic system is the proportion of a nation's economic activity consumed by the government. A measure of general government consumption as a proportion of GDP in 1960 is used.⁴ This World Bank measure includes all current expenditures for purchase of goods and services by central, regional, and local governments.⁵

Economic Development

Economic development is measured by the natural logarithm (ln) of energy consumption per capita in 1965⁶ (Taylor and Hudson, 1972). The utility of using energy consumption as an indicator of development is recognized by many social scientists. Work by Cottrell (1953; 1960) provides a multilinear theory of societal evolution based upon the role of energy. Within development theory, Levy (1966) has given the most attention to the importance of energy in the development process. In fact he defines development or modernization on the basis of the amount and uses of inanimate energy and tools.

The basic relationship that energy consumption has to development is also supported by empirical works. Darmstadter (1971) shows that there is a high correlation between per capita energy consumption and per capita GNP both cross-sectionally and over time. The amount of industrial capital stocks that a country has is central to its industrialization process.

⁴ The 1960 measure of government consumption was chosen because it had a more significant relationship to political democracy than either the 1965 or 1955 measure.

⁵ For a more detailed description of the components of this measure see World Bank (1976:6-7).

⁶ The 1965 measure of energy consumption was empirically chosen over a 1960 measure because of its closer relationship to the 1965 political democracy index. In the panel analysis reported later, the 1960 measure is used since the 1965 measure could not affect changes in political democracy from the earlier period 1960-65.

Frank (1959), testing time-series data, finds a correlation of 0.989 between energy consumption and industrial stock for the U.S. and a similar correlation for the U.K.

Using energy consumption also avoids some of the exchange rate and comparability problems that arise in using GNP and GDP. In addition energy consumption is often available for a larger and more representative sample of countries than is GNP or GDP.

The ln of energy consumption is used because there is empirical evidence that the relationship between development and democracy is curvilinear and can be best captured by a log transformation of energy consumption (Jackman, 1973). In addition the transformation reduces the extreme skewness in the untransformed energy consumption variable.

Political Democracy

Like many complex and abstract concepts in the social sciences, there are a number of possible definitions of political democracy. Common to many of these definitions are two dimensions: (1) popular sovereignty, and (2) political liberties. The first dimension, popular sovereignty, implies that the elites of a country must be accountable to the nonelites. The most common institution through which the nonelites exercise their control is through elections. In order for elections to represent popular sovereignty, there must be as wide a franchise as possible, equal weighting of votes and fair electoral processes. The second dimension, political liberties, is also essential to political democracy. Political liberties include the rights of free speech, a free press, and the right to organize against any officeholders or their policies.

One or both of these dimensions are found in other definitions of political democracy. Hewitt (1977:456-7), for instance, lists three characteristics of political democracy: (1) an elected chief executive (or executive responsible to elected assembly), (2) universal manhood suffrage, and (3) "fair" elections as represented by a secret ballot. All three of these

characteristics are indicators of popular sovereignty. Hewitt does not list any indicators of political liberties.

Lenski (1966:319) lists three criteria of political democracy: (1) universal adult suffrage, (2) the right of political opposition, and (3) the right of disadvantaged elements in the population to organize on their own behalf. This definition includes both of the dimensions discussed above; the first criterion indicates popular sovereignty and the second and third are elements of political liberties.

As illustrated by the preceding discussion there are numerous potential indicators of political democracy. But given the limited cross-national data that exists, the best that can be done is to attain a sample of all possible indicators of the construct, and to use these as measures of political democracy.

One goal in selecting indicators for this research is to choose those which are available for the largest possible sample of nations. It is important to have a democracy index that is representative of both developed and developing nations. Measures of political democracy used by Lipset (1963), Neubauer (1967), Cutright and Wiley (1969), and Hewitt (1977) do not have adequate coverage of less developed countries (LDC), whereas the measures of Coleman (1960) and Adelman and Morris (1973) do not include more developed countries (MDC). Those indices that contain both LDCs and MDCs, such as Jackman (1974; 1975), are often still not much larger than 60 to 80 countries.

It is also desirable to have an index that is available for more than one time period. In a later section of this paper a panel analysis will be used necessitating an index that is available for two time periods so that changes in political democracy can be analyzed. This goal of having measures at two time points conflicts with the goal of having a number of countries at varying levels of development. Since a significant proportion of the LDCs became independent in the late 1950s and early 1960s, not many indicators for them will be available before this time period. For example, Cutright and Wiley (1969) have a political representation index available for four ten-year periods extending back to

1927-36. But their sample is composed of only 40 countries. Coleman (1960), Lipset (1963), Cutright (1963), Neubauer (1967) and Jackman (1974; 1975) present indices for only one time-period.

Even more important to the selection of an index is the question of the validity of some of the indicators used in the political democracy indices (May, 1973). For example, a number of studies have failed to distinguish between political democracy and political stability. Lipset (1963), Cutright (1963), McCrone and Cnudde (1967), Smith (1969), Cutright and Wiley (1969), and Coulter (1975), among others, use an index that awards the highest scores to countries that are *stable* and *democratic*; "A scheme for scoring nations . . . should penalize each nation for political instability which represents 'backsliding' and reward it for achieving or retaining more complex political forms of organization" (Cutright, 1963:256).

Jackman (1975:86) claims that the failure to distinguish between stability and democracy has led to spurious findings in the study of political democracy's effects on economic equality.⁷ Spurious findings might also result in this research if one of these measures were used. This is because those countries that have been developing the longest are generally the most stable. A democracy measure incorporating stability in its construction would increase the chances of a positive relationship because of stability's positive association with the length of time a country has been developing. The confounding of stability and democracy in one index also complicates the study of changes in democracy. Although a country's level of democracy may change drastically over a five- or ten-year period (e.g., Brazil, 1960-65), an index aggregated over a ten- or twenty-year period may gloss over these changes.

Another variable that is related to political democracy, but can be conceptually

⁷ Jackman's argument has recently been critiqued by Robinson and Quinlan (1977), who claim that similar findings occur using either Jackman's democracy index or Cutright's. However, Robinson and Quinlan constructed Cutright's index over a shorter time period than originally used by Cutright, thereby lessening the very stability aspect that Jackman criticized (see Robinson and Quinlan, 1977: 613, fn. 4).

ally distinguished from it, is the percentage of the adult population voting. This indicator also has been used in a number of indices (e.g., Lerner, 1958; Smith, 1969; Jackman, 1975). Although having democratic institutions has no meaning without some popular participation, the percentage of the population voting in an election may reflect factors other than the extent of political democracy. For example, Kornhauser (1959) and Huntington (1968) argue that mass participation is considered desirable in both democratic and authoritarian regimes and therefore, high voting participation can be found in either type of society. Some countries require participation of all voters in elections so that participation statistics reflect a legal requirement rather than how democratic the system is. In addition, low levels of participation may result from either apathy of the voters or satisfaction with the government so that participation is viewed as not necessary (Lipset, 1963). A more pragmatic reason for not using participation statistics is that it is difficult if not impossible to get these statistics for a large number of LDCs and for more than one time period. A measure of the percentage of the population eligible to vote (the franchise) is a much better indicator of political democracy but an accurate measure of it is even more difficult to find than accurate participation statistics. These and other arguments (see May, 1973) suggest that using voting participation as an indicator of political democracy raises a number of difficulties.

Political democracy should also be distinguished from social democracy. A strong socialist or labor party in power may be crucial to reducing the inequalities in the distribution of social and economic goods, but such indicators of social democracy are analytically distinct from indicators of political democracy. "Political democracy is not a sufficient condition for the achievement of a more equal society. The crucial matter is what the mass electorate does with the franchise and other democratic procedures" (Hewitt, 1977: 451). In fact the relationship between political and social democracy is the subject of considerable research (see, e.g., Jackman, 1975; Hewitt, 1977). At

this point it seems best to treat these two concepts separately.

Because of the limitations in the other indices discussed above, a different index of political democracy is constructed. Of course there are a number of limitations which remain (e.g., no indicator of the popular support of government policies between elections), but the index has several advantages over existing ones.⁸ For example, it does not confound indicators of stability, voter turnout or economic equality with political democracy. In addition the index is available for over 120 countries in 1965 and 110 in 1960, including a large number of LDCs as well as MDCs.

The index consists of six components; three indicators of popular sovereignty and three of political liberties. The three measures of popular sovereignty are: (1) fairness of elections, (2) effective executive selection, and (3) legislative selection. The indicators of political liberties are: (4) freedom of the press, (5) freedom of group opposition, and (6) government sanctions. A description of each component and a correlation matrix of them is in the Appendix of this paper.⁹ Cronbach's (1951) alpha for the index is over .9, indicating high reliability. In addition, the index has moderate to high correlations with a number of other democracy indices (e.g., 0.70 with Adelman and Morris [1973], 0.79 with Jackman [1973], and 0.85 with Cutright and Wiley [1969]).

ANALYSIS

Hypotheses 1 and 2 represent the two most general propositions of this research. The first hypothesis suggests that the conditions favoring the rise of political democracy have deteriorated over time so

⁸ Several other limitations also can be mentioned. For example, there are no indicators of the class, sex, and race composition of the political elite. Nor is there a measure of how "open" the elite is in its recruitment of new members. Measures such as these would provide additional measures of popular sovereignty and the extent to which a "power elite" exists in countries which meet some of the other, more common conditions (e.g., fair elections and political liberties) of democracy.

⁹ A more complete discussion and presentation of the index is in preparation.

that the later a country begins to develop the less its chances for democracy. Hypothesis 2 states that the chances for democratic political systems have improved because of the worldwide diffusion of the democratic ideology.

These general hypotheses can be tested in the following regression equation:

$$Y = b_0 + b_1X_1 + b_2X_2 + e, \quad (1)$$

where Y = political democracy index, 1965,

X_1 = ln energy consumption per capita, 1965,

X_2 = Black's timing of development,

e = residual term.

Hypothesis 1 predicts that b_2 will be positive and significant; that is, the longer a country has been developing the greater its level of democracy. Hypothesis 2 suggests that b_2 will be negative and significant, so that the late developers are more likely to be democratic. The timing of development is correlated with the level of development ($r = 0.76$). This regression allows us to evaluate the general timing hypotheses compared with the effects of development. If the timing of development is more important than the level of development, the standardized regression coefficient for the timing variable should be greater than that for the level of development. If the level of development is more important, the opposite should be found.

The regression results are reported in Table 1. The coefficient for the timing of development variable (b_2) is positive as predicted by the first hypothesis but is not significantly different from zero.¹⁰ In

Table 1. Regression of Political Democracy Index on Black's Time of Development and ln Energy Consumption per Capita

Regressand	R ²	\bar{R}^2	F	Degrees of Freedom	N
Political Democracy 1965	.438	.426	37.4	2, 96	99
Regressor	Regression Coefficient* (Standard Error)		Standardized Regression Coefficient		
Time of Development	.026 (.054)		.056		
ln Energy Consumption per Capita 1965	10.2* (1.93)		.618		
Constant	.464				

* Regression coefficient significant at .05 level.

contrast, the coefficient for the level of development (b_1) is positive and highly significant ($p < 0.01$). This suggests that the *overall* effect of timing is not strongly positive or negative. The level of development is far more important in determining whether a country is democratic or not.

Since there is a moderately high correlation between the timing of development and the level of development, it is possible that multicollinearity is affecting the results. Multicollinearity refers to the interdependency of the independent variables in a regression analysis. When the interdependency is great, it is difficult to separate the unique effects of each collinear variable. As a result, the estimates of the regressor coefficients are likely to have large standard errors and are particularly susceptible to the effects of sampling fluctuations.

In Table 1, the timing of development, but not the development level, has a large standard error relative to the magnitude of its regression coefficient. Since there are only two independent variables in the regression (excluding the constant), the degree of collinearity for each variable is identical. If the correlation between these variables is the only factor leading to the nonsignificance of development timing, then the level of development should also have a large standard error, which it does not. However, it is possible that the particular sample configuration used resulted in the level of development being signifi-

¹⁰ There was some concern that the U.K., which began to develop long before any other country, might act as an outlier having a disproportionate effect on the estimate of the regression coefficients. To investigate this possibility, I reran the regression omitting the U.K. The regression estimates were not significantly different. As a further check on the possible impact of this type of outlier the democracy index was regressed on the natural log of the time of development. Again, no significant differences resulted. In this case it made the most sense to use the unlogged time of development variable including the U.K.

cant. Indeed if multicollinearity is a serious problem in this regression, a change in the sample should lead to very different results.

To test this possibility, I selected a random subsample of the full 99 cases and reran the regression.¹¹ The results were the same: the level of development was significant and development timing was not. Two additional random subsamples were analyzed with the same conclusion.

As an additional test of the general timing hypothesis another regression was run including the Rostow-Collier measure of the timing of development. The following regression equation was tested:

$$Y = b_0 + b_1X_1 + b_2X_2 + e, \quad (2)$$

where Y = political democracy index, 1965,

X_1 = ln energy consumption per capita, 1965,

X_2 = Rostow-Collier's economic take-off date,

e = residual term.

The results are reported in Table 2. As was found with Black's measure, the coefficient for the Rostow-Collier's take-off date is not significantly different from zero and the coefficient for development is positive and significant. Based on these consistent results across samples and measures of development timing, it is unlikely that multicollinearity can explain these findings.

The nonsignificant impact of the timing of development on political democracy does not rule out the possibility that more specific characteristics of development timing may affect democracy. As one possibility, Hypothesis 3 predicts that the greater extent to which a culture is Protestant-based, the more likely it is to be democratic. Hypothesis 4 suggests that a high degree of state controlled economic activity lessens the chances for political democracy. These two more specific hy-

Table 2. Regression of Political Democracy Index on Rostow-Collier's Take-Off Date and ln Energy Consumption per Capita

* Regression coefficient significant at .05 level.

¹¹ To select the random subsample, I assigned all countries a random number from a uniform distribution between zero and one. Those cases with a random number greater than 0.5 were analyzed.

0.56). However, both the percentage of the population that is Protestant and the state's economic strength measure have significant coefficients ($p < .05$) in the predicted direction. That is, the greater the proportion of the population that is Protestant, the higher the level of democracy, and the greater the proportion of GDP consumed by the government the less the level of democracy.¹² This equation also was estimated including Black's timing of development. The timing of development variable was still found to be insignificant as in Table 1.

Panel Design

Since development, Protestantism and the state's economic control are related to the level of political democracy, it is of interest to see if these same variables are related to *changes* in political democracy. The cross-sectional design is sometimes thought to represent more long-run relationships between variables. Those variables important in explaining cross-sectional variation may not have the same importance in explaining more short-run changes in political democracy. A panel design is one means to investigate this question. In panel analysis the dependent variable at time t is regressed on itself at an earlier time point along with the other independent variables. In this way it is possible to estimate the impact of the other independent variables on the dependent variable, while controlling for the earlier or lagged value of the dependent

** Significant at .10 level.

variable. The panel design used is represented in the following equation:

$$Y_t = b_0 + a_1 Y_{t-1} + b_1 X_1 + b_3 X_3 + b_4 X_4 + e, \quad (4)$$

Y_t = political democracy, 1965,

Y_{t-1} = political democracy, 1960,

X_1 = ln energy consumption per capita, 1960,

X_3 = percentage of population Protestant,

X_4 = state's control of economy, 1960,

e = residual term.

The results of this regression are reported in Table 4.¹³ The largest coefficient

¹² There was some concern that there may have been an interaction effect between development level and the state's control of the economy such that highly developed countries with economically strong governments have a different effect than predicted by the linear effects of these variables. For example, some of the social democracies of Europe, such as the U.K., Finland, Sweden, etc., have governments which consume and control a large percentage of GDP and are at high levels of development. Yet, their political systems are relatively democratic. It is possible, then, that a high development level combined with a strong government may have a significant impact. To test this, I reran equation (3) with an interaction term ($X_1 * X_4$) included. The interaction term proved not to be significant. This partially may have resulted because of the interaction term's high correlation with X_1 and X_4 .

¹³ Although panel estimation can provide information on the causes of changes in a dependent variable that are not available from a cross-sectional analysis (Heise, 1970), there are several cautionary remarks to be made. If there are unknown explanatory variables omitted from the equation (4), the residuals are likely to be autocorrelated. Autocorrelated residuals, in conjunction with the lagged dependent variable, will lead to bias and inconsistent estimates of the regression coefficients. With positively autocorrelated residuals the coefficient for the lagged dependent variable is generally biased upward and the remaining explanatory variable effects are biased toward zero (Hibbs, 1974:294-8). In equation (5) this means that the OLS estimate of a_1 , the coefficient of the earlier value of political democracy, is likely to be larger than the true effect and the esti-

is that associated with the lagged value of political democracy. The next largest standardized regression coefficient (0.23) is that for \ln energy consumption per capita. This variable's effect is significant at the 0.01 level. The state strength's regression coefficient is negative and significant at the 0.10 level (but not at the 0.05 level). Finally, the indicator of Protestantism is not significant in explaining the 1960 to 1965 changes in democracy. As was found for the previous regressions, the level of development's effects are more important than Protestantism or the state's control of the economic system. Equation (4) also was estimated including Black's timing of development. Once again it was found to be insignificant.

Although substantial changes in political democracy occurred in a number of countries between 1960 and 1965, a longer lag would allow for more changes in a greater number of countries. Because of data availability, the attempt to estimate any lags longer than five years leads to a tremendous drop in the number of LDCs in the sample. In addition, Monte Carlo simulations by Pelz and Lew (1970) suggest that the true effects of variables in a panel design may be exaggerated if too long a lag is chosen. However, there was some concern that the short lag involved in the estimation may have biased the results against finding stronger effects of Protestantism and the state's control of the economy. For this reason a ten-year lag model also was estimated. In the 49 countries for which data were available, the estimated coefficients for percent Protestant and state's economic control were even less significant than those reported in Table 4. However, if more data becomes available, further research on the lag would be worthwhile.

mated coefficients for development (energy consumption per capita), Protestantism, and state's economic control (b_1 , b_3 , and b_4 , respectively) will be underestimates of the true effects. Unfortunately, the simple panel design used here does not lend itself to the traditional tests of autocorrelation (e.g., Durbin-Watson test). For a more extensive discussion of panel estimation see Hannan and Young (1977).

DISCUSSION AND CONCLUSIONS

A number of social scientists have expressed considerable pessimism about the chances for political democracy in the late developers. The strains under which the latecomers must industrialize are viewed as something best handled by authoritarian governments. On the other hand, another perspective argues that with the diffusion of the democratic ideology over time, the latecomers increasingly will be under pressure to adopt more rather than less democratic forms of government. My research lends no support to either of these generalizations.

However, when more specific characteristics associated with development timing are examined, some significant effects are found. In the cases explored here, I have found support for the hypotheses that the greater the extent to which a culture is Protestant-based the greater the level of political democracy, and the greater the government's control of the economic system the lower the level of democracy.

In a panel analysis of *changes* in political democracy, the state's control of the economic system had negative effects as found in the "cross-sectional" regressions. Protestantism, however, did not appear to have any significant impact. In all of the regressions the most significant variable is the level of development. These results indicate that the level of development is a more important explanatory variable than the timing variables. However, a note of caution must be made in interpreting the null effect of the general timing variable. Although my results do not support the generalizations that conditions have become progressively worse or better for political democracy, these findings do not rule out the possibility that some of the more *specific* characteristics, such as differing cultural systems and economic dependency, have an effect. It is possible that the null effect of the time of development represents a "balancing out" of these positive and negative, more specific characteristics. In failing to find a general timing effect, this research has performed only a first step. Future research in this area should concentrate on

other specific timing variables (e.g., political instability, dependency, and rates of development) that may affect democracy and should compare their effects with development.

APPENDIX

The following is a brief description of the political democracy index for 1965. The 1960 political democracy index was constructed the same way except for a five-year change in time periods. A more detailed discussion of this index can be found in Bollen (1978: chap. 2).

The first component of the index, freedom of the press, is taken from Nixon (1965). The chief criterion for developing the measure is the degree of control normally exercised by any official agency which has the power to interfere with the dissemination and discussion of the news (Nixon, 1960: 17). Countries were rated by a panel of experts in the area of comparative journalism. The panel used reports from the International Press Institute, the Inter-American Press Association, and other country sources.

The second component, freedom of group opposition, classifies countries according to four levels: (1) no parties excluded, (2) one or more minor or "extremist" parties excluded, (3) significant exclusion of parties (or groups), and (4) no parties or all but the dominant party and its satellites excluded (Banks, 1971: segment 10, field 0). The average scores from 1964 to 1966 are used. If the measure is not available for three years, the average for those years with data in the three-year period is used. For this Bank's variable and the others used in the index, numerous country sources, newspapers, and journals were consulted for the ranking of nations. For a list of the primary sources see Banks (1971: Appendix 2).

The next component is a measure of elite political power as reflected in government sanctions. The sanctions include such actions as the closing of newspapers, censorship, restrictions on political participation, curfews, and the banning of groups opposing the government (Taylor and Hudson, 1971). Basic data for this indicator are in Taylor and Hudson (1971). A three-year average from 1964 to 1966 is used. The use of this variable as it appears in the original data set is biased against those societies which are relatively free to begin with. That is, those societies which are relatively free have more to lose than societies that already have many restrictions. In

order to correct for this bias, the number of elite sanctions is subtracted from an average "freedom" score formed by a country's freedom of the press and freedom of group opposition measures. This resulted in a higher correlation with the other five components than was found using the unadjusted elite sanction variable or its log.¹⁴

The fourth component, fairness of elections, ranges from: (1) no elections, (2) rigged elections, (3) substantial irregularity in elections, and (4) relatively free and competitive elections. This variable is the electoral irregularity variable for 1965 in Taylor and Hudson (1971). If no elections were held from 1961 to 1967 a country was scored as having no elections for 1965. Information on the number of elections during this period is from Taylor and Hudson (1971).

Effective executive selection is scored in two categories—elective and nonelective. This variable is from Banks (1971: segment 1, field j). The original "indirect elections" category was combined with the "elective." The "nonelective" category includes those societies having no elections from 1961 to 1967. A three-year average for this measure is computed for the years 1964 to 1966.

The final component, legislative selection, is formed by the combination of two variables. The first variable is a dichotomy describing whether the method of selecting the legislative body is nonelective or elective (Banks, 1971: segment 1, field p). Those countries in which no legislative body existed were scored as nonelective. The second variable used in this component is the effectiveness of the legislature (Banks, 1971: segment 10, field 1). Three levels of effectiveness are used: (1) ineffective, (2) partially effective, and (3) effective. The simple sum of these two measures has a questionable relationship to political democracy. An elected legislature that is powerless or ineffective does not indicate a

¹⁴ Using this corrective procedure involves a trade-off. The trade-off is that the correlations between the corrected elite sanctions and freedom of the press and freedom of group opposition are probably increased due to the use of these latter two freedoms in the corrective procedure. The benefit of the procedure is that the original government sanction variable by itself is of questionable validity as an indicator of political democracy because of its bias against those countries which have the most freedom to begin with. It is my judgment that the benefit of increasing validity outweighs any increase in the two correlations caused by a common component.

Table A1. Correlation Matrix of the Six Components in the 1960 Political Democracy Index

		X1	X2	X3	X4	X5	X6
Press Freedom	(X1)	1.0	.77	.79	.78	.61	.77
Freedom of Group Opposition	(X2)	.77	1.0	.86	.65	.54	.79
Elite Sanctions	(X3)	.79	.86	1.0	.68	.60	.76
Fairness of Elections	(X4)	.78	.65	.68	1.0	.58	.69
Executive Selection	(X5)	.61	.54	.60	.58	1.0	.68
Legislature Selection	(X6)	.77	.79	.76	.69	.68	1.0

All correlations significant at .001 level.

democratic system. Nor does an effective legislature that is appointed indicate democracy. Legislatures that are *both* elective and effective are more valid measures of political democracy. To capture the extent to which both conditions are met, the two variables are multiplied together to derive the sixth and final component of the political democracy index.

All six components were scored so that they ranged from zero to 100 with 100 indicating a high level of political democracy. Any country which had more than three of the six components missing were dropped. Values were estimated for nations having three or less missing components. Less than 10% of the variables needed to construct the index were estimated. The correlation matrix between the six components for 1960 is presented in Table A1.

SOCIAL CHANGE AND CRIME RATE TRENDS: A ROUTINE ACTIVITY APPROACH*

LAWRENCE E. COHEN AND MARCUS FELSON

University of Illinois, Urbana

American Sociological Review 1979, Vol. 44 (August):588-608.

In this paper we present a "routine activity approach" for analyzing crime rate trends and cycles. Rather than emphasizing the characteristics of offenders, with this approach we concentrate upon the circumstances in which they carry out predatory criminal acts. Most criminal acts require convergence in space and time of *likely offenders*, *suitable targets* and the *absence of capable guardians* against crime. Human ecological theory facilitates an investigation into the way in which social structure produces this convergence, hence allowing illegal activities to feed upon the legal activities of everyday life. In particular, we hypothesize that the dispersion of activities away from households and families increases the opportunity for crime and thus generates higher crime rates. A variety of data is presented in support of the hypothesis, which helps explain crime rate trends in the United States 1947-1974 as a byproduct of changes in such variables as labor force participation and single-adult households.

INTRODUCTION

In its summary report the National Commission on the Causes and Prevention of Violence (1969: xxxvii) presents an important sociological paradox:

Why, we must ask, have urban violent crime rates increased substantially during the past decade when the conditions that are supposed to cause violent crime have not worsened—have, indeed, generally improved?

The Bureau of the Census, in its latest report on trends in social and economic conditions in metropolitan areas, states that most "indicators of well-being point toward progress in the cities since 1960." Thus, for example, the proportion of blacks in cities who completed high school rose from 43 percent in 1960 to 61 percent in 1968; unemployment rates dropped significantly between 1959 and 1967 and the median family income of blacks in cities increased from 61 percent to 68 percent of the median white

family income during the same period. Also during the same period the number of persons living below the legally-defined poverty level in cities declined from 11.3 million to 8.3 million.

Despite the general continuation of these trends in social and economic conditions in the United States, the *Uniform Crime Report* (FBI, 1975:49) indicates that between 1960 and 1975 reported rates of robbery, aggravated assault, forcible rape and homicide increased by 263%, 164%, 174%, and 188%, respectively. Similar property crime rate increases reported during this same period¹ (e.g., 200% for burglary rate) suggest that the paradox noted by the Violence Commission applies to nonviolent offenses as well.

¹ Though official data severely underestimate crime, they at least provide a rough indicator of trends over time in the volume of several major felonies. The possibility that these data also reflect trends in rates at which offenses are reported to the police has motivated extensive victimology research (see Nettler, 1974; and Hindelang, 1976, for a review). This work consistently finds that seriousness of offense is the strongest determinant of citizen reporting to law enforcement officials (Skogan, 1976: 145; Hindelang, 1976: 401). Hence the upward trend in official crime rates since 1960 in the U.S. may reflect increases in *both* the volume and seriousness of offenses. Though disaggregating these two components may not be feasible, one may wish to interpret observed trends as generated largely by both.

For their comments, we thank David J. Bordua, Ross M. Stolzenberg, Christopher S. Dunn, Kenneth C. Land, Robert Schoen, Amos Hawley, and an anonymous reviewer. Funding for this study was provided by these United States Government grants: National Institute for Mental Health 1-R01-MH31117-01; National Science Foundation, SOC-77-13261; and United States Army RI/DAHC 19-76-G-0016. The authors' name order is purely alphabetical.

In the present paper we consider these paradoxical trends in crime rates in terms of changes in the "routine activities" of everyday life. We believe the structure of such activities influences criminal opportunity and therefore affects trends in a class of crimes we refer to as *direct-contact predatory violations*. Predatory violations are defined here as illegal acts in which "someone definitely and intentionally takes or damages the person or property of another" (Glaser, 1971:4). Further, this analysis is confined to those predatory violations involving direct physical contact between at least one offender and at least one person or object which that offender attempts to take or damage.

We argue that structural changes in routine activity patterns can influence crime rates by affecting the convergence in space and time of the three minimal elements of direct-contact predatory violations: (1) motivated offenders, (2) suitable targets, and (3) the absence of capable guardians against a violation. We further argue that the lack of any one of these elements is sufficient to prevent the successful completion of a direct-contact predatory crime, and that the convergence in time and space of suitable targets and the absence of capable guardians may even lead to large increases in crime rates without necessarily requiring any increase in the structural conditions that motivate individuals to engage in crime. That is, if the proportion of motivated offenders or even suitable targets were to remain stable in a community, changes in routine activities could nonetheless alter the likelihood of their convergence in space and time, thereby creating more opportunities for crimes to occur. Control therefore becomes critical. If controls through routine activities were to decrease, illegal predatory activities could then be likely to increase. In the process of developing this explanation and evaluating its consistency with existing data, we relate our approach to classical human ecological concepts and to several earlier studies.

The Structure of Criminal Activity

Sociological knowledge of how community structure generates illegal acts has

made little progress since Shaw and McKay and their colleagues (1929) published their pathbreaking work, *Delinquency Areas*. Variations in crime rates over space long have been recognized (e.g., see Guerry, 1833; Quetelet, 1842), and current evidence indicates that the pattern of these relationships within metropolitan communities has persisted (Reiss, 1976). Although most spatial research is quite useful for describing crime rate patterns and providing post hoc explanations, these works seldom consider—conceptually or empirically—the fundamental human ecological character of illegal acts as *events* which occur at specific locations in *space and time*, involving specific persons and/or objects. These and related concepts can help us to develop an extension of the human ecological analysis to the problem of explaining changes in crime rates over time. Unlike many criminological inquiries, we do not examine why individuals or groups are inclined criminally, but rather we take criminal inclination as given and examine the manner in which the spatio-temporal organization of social activities helps people to translate their criminal inclinations into action. Criminal violations are treated here as routine activities which share many attributes of, and are interdependent with, other routine activities. This interdependence between the structure of illegal activities and the organization of everyday subsistence activities leads us to consider certain concepts from human ecological literature.

Selectec' Concepts from Hawley's Human Ecological Theory

While criminologists traditionally have concentrated on the *spatial* analysis of crime rates within metropolitan communities, they seldom have considered the *temporal* interdependence of these acts. In his classic theory of human ecology, Amos Hawley (1950) treats the community not simply as a unit of territory but rather as an organization of symbiotic and commensalistic relationships as human activities are performed over both space and time.

Hawley identified three important temporal components of community structure: (1) *rhythm*, the regular periodicity with which events occur, as with the rhythm of travel activity; (2) *tempo*, the number of events per unit of time, such as the number of criminal violations per day on a given street; and (3) *timing*, the coordination among different activities which are more or less interdependent, such as the coordination of an offender's rhythms with those of a victim (Hawley, 1950:289; the examples are ours). These components of temporal organization, often neglected in criminological research, prove useful in analyzing how illegal tasks are performed—a utility which becomes more apparent after noting the spatio-temporal requirements of illegal activities.

The Minimal Elements of Direct-Contact Predatory Violations

As we previously stated, despite their great diversity, direct-contact predatory violations share some important requirements which facilitate analysis of their structure. Each successfully completed violation minimally requires an *offender* with both criminal inclinations and the ability to carry out those inclinations, a person or object providing a *suitable target* for the offender, and *absence of guardians* capable of preventing violations. We emphasize that the lack of any one of these elements normally is sufficient to prevent such violations from occurring.² Though guardianship is implicit in everyday life, it usually is marked by the absence of violations; hence it is easy to overlook. While police action is analyzed widely, guardianship by ordinary citizens of one another and of property as they go about routine activities may be one of the most neglected elements in sociological research on crime, especially since it links seemingly unre-

lated social roles and relationships to the occurrence or absence of illegal acts.

The conjunction of these minimal elements can be used to assess how social structure may affect the tempo of each type of violation. That is, the probability that a violation will occur at any specific time and place might be taken as a function of the convergence of likely offenders and suitable targets in the absence of capable guardians. Through consideration of how trends and fluctuations in social conditions affect the frequency of this convergence of criminogenic circumstances, an explanation of temporal trends in crime rates can be constructed.

The Ecological Nature of Illegal Acts

This ecological analysis of direct-contact predatory violations is intended to be more than metaphorical. In the context of such violations, people, gaining and losing sustenance, struggle among themselves for property, safety, territorial hegemony, sexual outlet, physical control, and sometimes for survival itself. The interdependence between offenders and victims can be viewed as a predatory relationship between functionally dissimilar individuals or groups. Since predatory violations fail to yield any net gain in sustenance for the larger community, they can only be sustained by feeding upon other activities. As offenders cooperate to increase their efficiency at predatory violations and as potential victims organize their resistance to these violations, both groups apply the symbiotic principle to improve their sustenance position. On the other hand, potential victims of predatory crime may take evasive actions which encourage offenders to pursue targets other than their own. Since illegal activities must feed upon other activities, the spatial and temporal structure of routine legal activities should play an important role in determining the location, type and quantity of illegal acts occurring in a given community or society. Moreover, one can analyze how the structure of community organization as well as the level of technology in a society provide the circumstances under which crime can thrive. For example, technology and organization

² The analytical distinction between target and guardian is not important in those cases where a personal target engages in self-protection from direct-contact predatory violations. We leave open for the present the question of whether a guardian is effective or ineffective in all situations. We also allow that various guardians may primarily supervise offenders, targets or both. These are questions for future examination.

affect the capacity of persons with criminal inclinations to overcome their targets, as well as affecting the ability of guardians to contend with potential offenders by using whatever protective tools, weapons and skills they have at their disposal. Many technological advances designed for legitimate purposes—including the automobile, small power tools, hunting weapons, highways, telephones, etc.—may enable offenders to carry out their own work more effectively or may assist people in protecting their own or someone else's person or property.

Not only do routine legitimate activities often provide the wherewithal to commit offenses or to guard against others who do so, but they also provide offenders with suitable targets. Target suitability is likely to reflect such things as value (i.e., the material or symbolic desirability of a personal or property target for offenders), physical visibility, access, and the inertia of a target against illegal treatment by offenders (including the weight, size, and attached or locked features of property inhibiting its illegal removal and the physical capacity of personal victims to resist attackers with or without weapons). Routine production activities probably affect the suitability of consumer goods for illegal removal by determining their value and weight. Daily activities may affect the location of property and personal targets in visible and accessible places at particular times. These activities also may cause people to have on hand objects that can be used as weapons for criminal acts or self-protection or to be preoccupied with tasks which reduce their capacity to discourage or resist offenders.

While little is known about conditions that affect the convergence of potential offenders, targets and guardians, this is a potentially rich source of propositions about crime rates. For example, daily work activities separate many people from those they trust and the property they value. Routine activities also bring together at various times of day or night persons of different background, sometimes in the presence of facilities, tools or weapons which influence the commission or avoidance of illegal acts. Hence, the timing of work, schooling and leisure may

be of central importance for explaining crime rates.

The ideas presented so far are not new, but they frequently are overlooked in the theoretical literature on crime. Although an investigation of the literature uncovers significant examples of descriptive and practical data related to the routine activities upon which illegal behavior feeds, these data seldom are treated within an analytical framework. The next section reviews some of this literature.

RELATION OF THE ROUTINE ACTIVITY APPROACH TO EXISTANT STUDIES

A major advantage of the routine activity approach presented here is that it helps assemble some diverse and previously unconnected criminological analyses into a single substantive framework. This framework also serves to link illegal and legal activities, as illustrated by a few examples of descriptive accounts of criminal activity.

Descriptive Analyses

There are several descriptive analyses of criminal acts in criminological literature. For example, Thomas Reppetto's (1974) study, *Residential Crime*, considers how residents supervise their neighborhoods and streets and limit access of possible offenders. He also considers how distance of households from the central city reduces risks of criminal victimization. Reppetto's evidence—consisting of criminal justice records, observations of comparative features of geographic areas, victimization survey data and offender interviews—indicates that offenders are very likely to use burglary tools and to have at least minimal technical skills, that physical characteristics of dwellings affect their victimization rates, that the rhythms of residential crime rate patterns are marked (often related to travel and work patterns of residents), and that visibility of potential sites of crime affects the risk that crimes will occur there. Similar findings are reported by Pope's (1977a; 1977b) study of burglary in California and by Scarr's (1972) study of burglary in and around the District of Columbia. In addi-

tion, many studies report that architectural and environmental design as well as community crime programs serve to decrease target suitability and increase capable guardianship (see, for example, Newman, 1973; Jeffery, 1971; Washnis, 1976), while many biographical or autobiographical descriptions of illegal activities note that lawbreakers take into account the nature of property and/or the structure of human activities as they go about their illegal work (see, e.g., Chambliss, 1972; Klockars, 1974; Sutherland, 1937; Letkemann, 1973; Jackson, 1969; Martin, 1952; Maurer, 1964; Cameron, 1964; Williamson, 1968).

Evidence that the spatio-temporal organization of society affects patterns of crime can be found in several sources. Strong variations in specific predatory crime rates from hour to hour, day to day, and month to month are reported often (e.g., Wolfgang, 1958; Amir, 1971; Rappetto, 1974; Scarr, 1972; FBI, 1975; 1976), and these variations appear to correspond to the various tempos of the related legitimate activities upon which they feed. Also at a microsociological level, Short and Strodtbeck (1965: chaps. 5 and 11) describe opportunities for violent confrontations of gang boys and other community residents which arise in the context of community leisure patterns, such as "quarter parties" in black communities, and the importance, in the calculus of decision making employed by participants in such episodes, of low probabilities of legal intervention. In addition, a wealth of empirical evidence indicates strong spatial variations over community areas in crime and delinquency rates³ (for an excellent discussion and re-

view of the literature on ecological studies of crimes, see Wilks, 1967). Recently, Albert Reiss (1976) has argued convincingly that these spatial variations (despite some claims to the contrary) have been supported consistently by both official and unofficial sources of data. Reiss further cites victimization studies which indicate that offenders are very likely to select targets not far from their own residence (see USDJ, 1974a; 1974b; 1974c).

Macrolevel Analyses of Crime Trends and Cycles

Although details about how crime occurs are intrinsically interesting, the important analytical task is to learn from these details how illegal activities carve their niche within the larger system of activities. This task is not an easy one. For example, attempts by Bonger (1916), Durkheim (1951; 1966), Henry and Short (1954), and Fleisher (1966) to link the rate of illegal activities to the economic condition of a society have not been completely successful. Empirical tests of the relationships postulated in the above studies have produced inconsistent results which some observers view as an indication that the level of crime is not related systematically to the economic conditions of a society (Mansfield et al., 1974: 463; Cohen and Felson, 1979).

It is possible that the wrong economic and social factors have been employed in these macro studies of crime. Other researchers have provided stimulating alternative descriptions of how social change affects the criminal opportunity structure, thereby influencing crime rates in particular societies. For example, at the beginning of the nineteenth century, Patrick Colquhoun (1800) presented a detailed, lucid description and analysis of crime in the London metropolitan area and suggestions for its control. He assembled substantial evidence that London was experiencing a massive crime wave attributable to a great increment in the assemblage and

³ One such ecological study by Sarah Boggs (1965) presents some similar ideas in distinguishing *familiarity* of offenders with their targets and *profitability* of targets as two elements of crime occurrence. Boggs's work stands apart from much research on the ecology of crime in its consideration of crime occurrence rates separately from offender rates. The former consist of the number of offenses committed in a given area per number of suitable targets within that area (as estimated by various indicators). The latter considers the residence of offenders in computing the number of offenders per unit of population. Boggs examines the correlations between crime occurrence rates and offender rates for several of-

fenses in St. Louis and shows that the two are often independent. It appears from her analysis that *both* target and offender characteristics play a central role in the location of illegal activity.

movement of valuable goods through its ports and terminals.

A similar examination of crime in the period of the English industrial expansion was carried out by a modern historian, J. J. Tobias (1967), whose work on the history of crime in nineteenth century England is perhaps the most comprehensive effort to isolate those elements of social change affecting crime in an expanding industrial nation. Tobias details how far-reaching changes in transportation, currency, technology, commerce, merchandising, poverty, housing, and the like, had tremendous repercussions on the amount and type of illegal activities committed in the nineteenth century. His thesis is that structural transformations either facilitated or impeded the opportunities to engage in illegal activities. In one of the few empirical studies of how recent social change affects the opportunity structure for crime in the United States, Leroy Gould (1969) demonstrated that the increase in the circulation of money and the availability of automobiles between 1921 and 1965 apparently led to an increase in the rate of bank robberies and auto thefts, respectively. Gould's data suggest that these relationships are due more to the abundance of opportunities to perpetrate the crimes than to short-term fluctuations in economic activities.

Although the sociological and historical studies cited in this section have provided some useful *empirical* generalizations and important insights into the incidence of crime, it is fair to say that they have not articulated systematically the *theoretical* linkages between routine legal activities and illegal endeavors. Thus, these studies cannot explain how changes in the larger social structure generate changes in the opportunity to engage in predatory crime and hence account for crime rate trends.⁴

To do so requires a conceptual framework such as that sketched in the preceding section. Before attempting to demonstrate the feasibility of this approach with macrolevel data, we examine available microlevel data for its consistency with the major assumptions of this approach.

Microlevel Assumptions of the Routine Activity Approach

The theoretical approach taken here specifies that crime rate trends in the post-World War II United States are related to patterns of what we have called routine activities. We define these as any recurrent and prevalent activities which provide for basic population and individual needs, whatever their biological or cultural origins. Thus routine activities would include formalized work, as well as the provision of standard food, shelter, sexual outlet, leisure, social interaction, learning and childrearing. These activities may go well beyond the minimal levels needed to prevent a population's extinction, so long as their prevalence and recurrence makes them a part of everyday life.

Routine activities may occur (1) at home, (2) in jobs away from home, and (3) in other activities away from home. The latter may involve primarily household members or others. We shall argue that, since World War II, the United States has experienced a major shift of routine activities away from the first category into the remaining ones, especially those nonhousehold activities involving nonhousehold members. In particular, we shall argue that this shift in the structure of routine activities increases the probability that motivated offenders will converge in space and time with suitable targets in the absence of capable guardians, hence contributing to significant increases in the

⁴ The concept of the opportunity for crime contained in the above research and in this study differs considerably from the traditional sociological usage of the *differential opportunity* concept. For example, Cloward and Ohlin (1960) employed this term in discussing how legitimate and illegitimate opportunities affect the resolution of adjustment problems leading to gang delinquency. From their viewpoint, this resolution depends upon the kind of social support for one or another type of illegitimate activity that is

given at different points in the social structure (Cloward and Ohlin, 1960: 151). Rather than circumstantial determinants of crime, they use differential opportunity to emphasize structural features which motivate offenders to perpetrate certain types of crimes. Cloward and Ohlin are largely silent on the interaction of this motivation with target suitability and guardianship as this interaction influences crime rates.

direct-contact predatory crime rates over these years.

If the routine activity approach is valid, then we should expect to find evidence for a number of empirical relationships regarding the nature and distribution of predatory violations. For example, we would expect routine activities performed within or near the home and among family or other primary groups to entail lower risk of criminal victimization because they enhance guardianship capabilities. We should also expect that routine daily activities affect the location of property and personal targets in visible and accessible places at particular times, thereby influencing their risk of victimization. Furthermore, by determining their size and weight and in some cases their value, routine production activities should affect the suitability of consumer goods for illegal removal. Finally, if the routine activity approach is useful for explaining the paradox presented earlier, we should find that the circulation of people and property, the size and weight of consumer items etc., will parallel changes in crime rate trends for the post-World War II United States.

The veracity of the routine activity approach can be assessed by analyses of both microlevel and macrolevel interdependencies of human activities. While consistency at the former level may appear noncontroversial, or even obvious, one nonetheless needs to show that the approach does not contradict existing data before proceeding to investigate the latter level.

EMPIRICAL ASSESSMENT

Circumstances and Location of Offenses

The routine activity approach specifies that household and family activities entail lower risk of criminal victimization than nonhousehold-nonfamily activities, despite the problems in measuring the former.⁵

⁵ Recent research indicates the existence of substantial quantities of family violence which remains outside of UCR data (see annotated bibliography of family violence in Lystad, 1974). While we cannot rule out the likelihood that much family violence is concealed from victimization surveys, the latter capture information absent from police data and still

National estimates from large-scale government victimization surveys in 1973 and 1974 support this generalization (see methodological information in Hindelang et al., 1976: Appendix 6). Table 1 presents several incident-victimization rates per 100,000 population ages 12 and older. Clearly, the rates in Panels A and B are far lower at or near home than elsewhere and far lower among relatives than others. The data indicate that risk of victimization varies directly with social distance between offender and victim. Panel C of this table indicates, furthermore, that risk of lone victimization far exceeds the risk of victimization for groups. These relationships are strengthened by considering time budget evidence that, on the average, Americans spend 16.26 hours per day at home, 1.38 hours on streets, in parks, etc., and 6.36 hours in other places (Szalai, 1972:795). Panel D of Table 1 presents our estimates of victimization per billion person-hours spent in such locations.⁶ For example, personal larceny

indicate that nonfamily members are usually much more dangerous than family members are to each other (see text). Also, when family violence leads to death, its suppression becomes quite difficult. The murder circumstances data indicate that about two-thirds of killings involve nonrelatives. Without denying the evidence that the level of family violence is far greater than police reports would indicate, available data also suggest that time spent in family activities within households incurs less risk of victimization than many alternative activities in other places. In addition, many of the most common offenses (such as robbery and burglary) always have been recognized as usually involving nonfamily members.

⁶ Billion person-hours can easily be conceptualized as 1,000,000 persons spending 1,000 hours each (or about 42 days) in a given location (Szalai, 1972:795). Fox obtained these data from a 1966 time budget study in 44 American cities. The study was carried out by the Survey Research Center, the University of Michigan. We combined four subsamples in computing our figures. We combined activities into three locations, as follows: (1) at or just outside home; (2) at another's home, restaurants or bars, or indoor leisure; (3) in streets, parks, or outdoor leisure. Our computing formula was

$$Q = [(R \div 10^5) \div (A \cdot 365)] \cdot 10^9,$$

where Q is the risk per billion person-hours; R is the victimization rate, reported per 10⁵ persons in Hindelang et al. (1976: Table 318); A is the hours spent per location calculated from Szalai (1972: 795); 365 is the multiplier to cover a year's exposure to risk; and 10⁹ converts risk per person-hour to billion person-hours.

Table 1. Incident-Specific Risk Rates for Rape, Robbery, Assault and Personal Larceny with Contact, United States, 1974

		Rape	Robbery	Assault	Personal Larceny with Contact	Total

	Street, Nonstranger	179	735	5,777	496	7,167
	Elsewhere, Stranger	129	513	1,934	2,455	4,988
	Elsewhere, Nonstranger	47	155	1,544	99	1,874

* * Calculated from Handelang et al., 1977: Tables 3.16, 3.18, 3.27, 3.28. Rates are per 100,000 persons ages 12 and over.

** See fn. 6 for source. Rates are per billion person-hours in stated locations.

*** Based on white data only due to lack of suitable sample size for nonwhites as victims of rape with multiple offenders.

rates (with contact) are 350 times higher at the hands of strangers in streets than at the hands of nonstrangers at home. Separate computations from 1973 victimization data (USDJ, 1976: Table 48) indicate that there were two motor vehicle thefts per million vehicle-hours parked at or near home, 55 per million vehicle-hours in streets, parks, playgrounds, school grounds or parking lots, and 12 per million vehicle-hours elsewhere. While the direction of these relationships is not surprising, their magnitudes should be noted. It appears that risk of criminal victimization varies dramatically among the circumstances and locations in which people place themselves and their property.

Target Suitability

Another assumption of the routine activity approach is that target suitability influences the occurrence of direct-contact predatory violations. Though we lack data

to disaggregate all major components of target suitability (i.e., value, visibility, accessibility and inertia), together they imply that expensive and movable durables, such as vehicles and electronic appliances, have the highest risk of illegal removal.

As a specific case in point, we compared the 1975 composition of stolen property reported in the Uniform Crime Report (FBI, 1976: Tables 26-7) with national data on personal consumer expenditures for goods (CEA, 1976: Tables 13-16) and to appliance industry estimates of the value of shipments the same year (*Merchandising Week*, 1976). We calculated that \$26.44 in motor vehicles and parts were stolen for each \$100 of these goods consumed in 1975, while \$6.82 worth of electronic appliances were stolen per \$100 consumed. Though these estimates are subject to error in citizen and police estimation, what is important here is their size relative to other rates. For example, only

8¢ worth of nondurables and 12¢ worth of furniture and nonelectronic household durables were stolen per \$100 of each category consumed, the motor vehicle risk being, respectively, 330 and 220 times as great. Though we lack data on the "stocks" of goods subject to risk, these "flow" data clearly support our assumption that vehicles and electronic appliances are greatly overrepresented in thefts.

The 1976 Buying Guide issue of *Consumer Reports* (1975) indicates why electronic appliances are an excellent retail value for a thief. For example, a Panasonic car tape player is worth \$30 per lb., and a Phillips phonograph cartridge is valued at over \$5,000 per lb., while large appliances such as refrigerators and washing machines are only worth \$1 to \$3 per lb. Not surprisingly, burglary data for the District of Columbia in 1969 (Scarr, 1972: Table 9) indicate that home entertainment items alone constituted nearly four times as many stolen items as clothing; food, drugs, liquor, and tobacco combined and nearly eight times as many stolen items as office supplies and equipment. In addition, 69% of national thefts classified in 1975 (FBI, 1976: Tables 1, 26) involve automobiles, their parts or accessories, and thefts from automobiles or thefts of bicycles. Yet radio and television sets plus electronic components and accessories totaled only 0.10% of the total truckload tonnage terminated in 1973 by intercity motor carriers, while passenger cars, motor vehicle parts and accessories, motorcycles, bicycles, and their parts, totaled only 5.5% of the 410 million truckload tons terminated (ICC, 1974). Clearly, portable and movable durables are reported stolen in great disproportion to their share of the value and weight of goods circulating in the United States.

Family Activities and Crime Rates

One would expect that persons living in single-adult households and those employed outside the home are less obligated to confine their time to family activities within households. From a routine activity perspective, these persons and their households should have higher rates of

predatory criminal victimization. We also expect that adolescents and young adults who are perhaps more likely to engage in peer group activities rather than family activities will have higher rates of criminal victimization. Finally, married persons should have lower rates than others. Tables 2 and 3 largely confirm these expectations (with the exception of personal larceny with contact). Examining these tables, we note that victimization rates appear to be related inversely to age and are lower for persons in "less active" statuses (e.g., keeping house, unable to work, retired) and persons in intact marriages. A notable exception is indicated in Table 2, where persons unable to work appear more likely to be victimized by rape, robbery and personal larceny with contact than are other "inactive persons." Unemployed persons also have unusually high rates of victimization. However, these rates are consistent with the routine activity approach offered here: the high rates of victimization suffered by the unemployed may reflect their residential proximity to high concentrations of potential offenders as well as their age and racial composition, while handicapped persons have high risk of personal victimization because they are less able to resist motivated offenders. Nonetheless, persons who keep house have noticeably lower rates of victimization than those who are employed, unemployed, in school or in the armed forces.

As Table 3 indicates, burglary and robbery victimization rates are about twice as high for persons living in single-adult households as for other persons in each age group examined. Other victimization data (USDJ, 1976: Table 21) indicate that, while household victimization rates tend to vary directly with household size, larger households have lower rates per person. For example, the total household victimization rates (including burglary, household larceny, and motor vehicle theft) per 1,000 households were 168 for single-person households and 326 for households containing six or more persons. Hence, six people distributed over six single-person households experience an average of 1,008 household victimizations, more than three times as many as

Table 2. Selected Status-Specific Personal Victimization Rates for the United States (per 100,000 Persons in Each Category)

Variables and Sources	Victim Category	Rape	Robbery	Assault	Personal Larceny with Contact	Personal Larceny without Contact
A. AGE (Source: Hindelang, et al., 1977: Table 310, 1974 rates)	12-15	147	1,267	3,848	311	16,355

	Widowed	—	450	590	480	2,460

Line indicates too few offenses for accurate estimates of rate. However, rates in these cells are usually small.

one six-person household. Moreover, age of household head has a strong relationship to a household's victimization rate for these crimes. For households headed

by persons under 20, the motor vehicle theft rate is nine times as high, and the burglary and household larceny rates four times as high as those for households headed by persons 65 and over (USDJ, 1976: Table 9).

While the data presented in this section were not collected originally for the purpose of testing the routine activity approach, our efforts to rework them for these purposes have proven fruitful. The routine activity approach is consistent with the data examined and, in addition, helps to accommodate within a rather simple and coherent analytical framework certain findings which, though not necessarily new, might otherwise be attributed only "descriptive" significance. In the next section, we examine macrosocial

Table 3. Robbery-Burglary Victimization Rates by Ages and Number of Adults in Household, 1974 and 1976 General Social Survey

Age	Number of Adults in Household		Ratio
	One	Two or More	
18-35	0.200 (140)	0.095 (985)	2.11
36-55	0.161 (112)	0.079 (826)	2.04
56 and over	0.107 (262)	0.061 (640)	1.76
All Ages	0.144 (514)	0.081 (2451)	1.78

trends as they relate to trends in crime rates.

CHANGING TRENDS IN ROUTINE ACTIVITY STRUCTURE AND PARALLEL TRENDS IN CRIME RATES

The main thesis presented here is that the dramatic increase in the reported crime rates in the U.S. since 1960 is linked to changes in the routine activity structure of American society and to a corresponding increase in target suitability and decrease in guardian presence. If such a thesis has validity, then we should be able to identify these social trends and show how they relate to predatory criminal victimization rates.

Trends in Human Activity Patterns

The decade 1960-1970 experienced noteworthy trends in the activities of the American population. For example, the percent of the population consisting of female college students increased 118% (USBC, 1975: Table 225). Married female labor force participant rates increased 31% (USBC, 1975: Table 563), while the percent of the population living as primary individuals increased by 34% (USBC, 1975: Table 51; see also Kobrin, 1976). We gain some further insight into changing routine activity patterns by comparing hourly data for 1960 and 1971 on households *unattended* by persons ages 14 or over when U.S. census interviewers first called (see Table 4). These data suggest that the proportion of households unattended at 8 A.M. increased by almost half between 1960 and 1971. One also finds increases in rates of out-of-town travel, which provides greater opportunity for both daytime and nighttime burglary of residences. Between 1960 and 1970, there was a 72% increase in state and national park visits per capita (USBC, 1975), an 144% increase in the percent of plant workers eligible for three weeks vacation (BLS, 1975: Table 116), and an 184% increase in overseas travellers per 100,000 population (USBC, 1975: Table 366). The National Travel Survey, conducted as part of the U.S. Census Bureau's Census of Transportation, confirms the general

Table 4. Proportion of Households Unattended by Anyone 14 Years Old or Over by Time of Day during First Visit by Census Bureau Interviewer, 1960 and 1971

Time of day	November, 1971

trends, tallying an 81% increase in the number of vacations taken by Americans from 1967 to 1972, a five-year period (USBC, 1973a: Introduction).

The dispersion of activities away from households appears to be a major recent social change. Although this decade also experienced an important 31% increase in the percent of the population ages 15-24, age structure change was only one of many social trends occurring during the period, especially trends in the circulation of people and property in American society.⁷

The importance of the changing activity structure is underscored by taking a brief look at demographic changes between the years 1970 and 1975, a period of continuing crime rate increments. Most of the recent changes in age structure relevant to crime rates already had occurred by 1970; indeed, the proportion of the population ages 15-24 increased by only 6% between 1970 and 1975, compared with a 15% increase during the five years 1965 to 1970. On the other hand, major changes in the structure of routine activities continued

⁷ While the more sophisticated treatments of the topic have varied somewhat in their findings, most recent studies attempting to link crime rate increases to the changing age structure of the American population have found that the latter account for a relatively limited proportion of the general crime trend (see, for example, Sagi and Wellford, 1968; Ferdinand, 1970; and Wellford, 1973).

during these years. For example, in only five years, the estimated proportion of the population consisting of husband-present, married women in the labor force households increased by 11%, while the estimated number of non-husband-wife households per 100,000 population increased from 9,150 to 11,420, a 25% increase (USBC, 1976: Tables 50, 276; USBC, 1970-1975). At the same time, the percent of population enrolled in higher education increased 16% between 1970 and 1975.

Related Property Trends and Their Relation to Human Activity Patterns

Many of the activity trends mentioned above normally involve significant investments in durable goods. For example, the dispersion of population across relatively more households (especially non-husband-wife households) enlarges the market for durable goods such as television sets and automobiles. Women participating in the labor force and both men and women enrolled in college provide a market for automobiles. Both work and travel often involve the purchase of major movable or portable durables and their use away from home.

Considerable data are available which indicate that sales of consumer goods changed dramatically between 1960 and 1970 (as did their size and weight), hence providing more suitable property available for theft. For example, during this decade, constant-dollar personal consumer expenditures in the United States for motor vehicles and parts increased by 71%, while constant-dollar expenditures for other durables increased by 105% (calculated from CEA, 1976: Table B-16). In addition, electronic household appliances and small houseware shipments increased from 56.2 to 119.7 million units (*Electrical Merchandising Week*, 1964; *Merchandising Week*, 1973). During the same decade, appliance imports increased in value by 681% (USBC, 1975: Table 1368).

This same period appears to have spawned a revolution in small durable product design which further feeds the opportunity for crime to occur. Relevant data from the 1960 and 1970 Sears catalogs

on the weight of many consumer durable goods were examined. Sears is the nation's largest retailer and its policy of purchasing and relabeling standard manufactured goods makes its catalogs a good source of data on widely merchandised consumer goods. The lightest television listed for sale in 1960 weighed 38 lbs., compared with 15 lbs. for 1970. Thus, the lightest televisions were 2½ times as heavy in 1960 as 1970. Similar trends are observed for dozens of other goods listed in the Sears catalog. Data from *Consumer Reports Buying Guide*, published in December of 1959 and 1969, show similar changes for radios, record players, slide projectors, tape recorders, televisions, toasters and many other goods. Hence, major declines in weight between 1960 and 1970 were quite significant for these and other goods, which suggests that the consumer goods market may be producing many more targets suitable for theft. In general, one finds rapid growth in property suitable for illegal removal and in household and individual exposure to attack during the years 1960-1975.

Related Trends in Business Establishments

Of course, as households and individuals increased their ownership of small durables, businesses also increased the value of the merchandise which they transport and sell as well as the money involved in these transactions. Yet the Census of Business conducted in 1958, 1963, 1967, and 1972 indicate that the number of wholesale, retail, service, and public warehouse establishments (including establishments owned by large organizations) was a nearly constant ratio of one for every 16 persons in the United States. Since more goods and money were distributed over a relatively fixed number of business establishments, the tempo of business activity per establishment apparently was increasing. At the same time, the percent of the population employed as sales clerks or salesmen in retail trade declined from 1.48% to 1.27%, between 1960 and 1970, a 14.7% decline (USBC, 1975: Table 589).

Though both business and personal

property increased, the changing pace of activities appears to have exposed the latter to greater relative risk of attack, whether at home or elsewhere, due to the dispersion of goods among many more households, while concentrating goods in business establishments. However, merchandise in retail establishments with heavy volume and few employees to guard it probably is exposed to major increments in risk of illegal removal than is most other business property.

Composition of Crime Trends

If these changes in the circulation of people and property are in fact related to crime trends, the *composition* of the latter should reflect this. We expect relatively greater increases in personal and household victimization as compared with most business victimizations, while shoplifting should increase more rapidly than other types of thefts from businesses. We expect personal offenses at the hands of strangers to manifest greater increases than such offenses at the hands of nonstrangers. Finally, residential burglary rates should increase more in daytime than nighttime.

The available time series on the composition of offenses confirm these expectations. For example, Table 5 shows that commercial burglaries declined from 60% to 36% of the total, while daytime residential burglaries increased from 16% to 33%. Unlike the other crimes against business, shoplifting increased its share. Though we lack trend data on the circumstances of other violent offenses, murder data confirm our expectations. Between 1963 and 1975, felon-type murders increased from 17% to 32% of the total. Compared with a 47% increase in the rate of relative killings in this period, we calculated a 294% increase in the murder rate at the hands of known or suspected felon types.

Thus the trends in the composition of recorded crime rates appear to be highly consistent with the activity structure trends noted earlier. In the next section we apply the routine activity approach in order to model crime rate trends and social change in the post-World War II United States.

Table 5. Offense Analysis Trends for Robbery, Burglary, Larceny and Murder; United States, 1960-1975

A. ROBBERIES ^a				
	1960	1965	1970

^a Excluding miscellaneous robberies. The 1975 distribution omitted due to apparent instability of post-1970 data.

^b Includes romantic triangles, lovers' quarrels and arguments.

^c Includes both known and suspected felon types.

THE RELATIONSHIP OF THE HOUSEHOLD ACTIVITY RATIO TO FIVE ANNUAL OFFICIAL INDEX CRIME RATES IN THE UNITED STATES, 1947-1974

In this section, we test the hypothesis that aggregate official crime rate trends in the United States vary directly over time with the dispersion of activities away from family and household. The limitations of annual time series data do not allow construction of direct measures of changes in hourly activity patterns, or quantities, qualities and movements of exact stocks of household durable goods, but the Current Population Survey does provide related time series on labor force and household structure. From these data, we calculate annually (beginning in 1947) a household activity ratio by adding the number of married, husband-present female labor force participants (source: BLS, 1975: Table 5) to the number of non-husband-wife households (source: USBC, 1947-1976), dividing this sum by

the total number of households in the U.S. (source: USBC, 1947–1976). This calculation provides an estimate of the proportion of American households in year t expected to be most highly exposed to risk of personal and property victimization due to the dispersion of their activities away from family and household and/or their likelihood of owning extra sets of durables subject to high risk of attack. Hence, the household activity ratio should vary directly with official index crime rates.

Our empirical goal in this section is to test this relationship, with controls for those variables which other researchers have linked empirically to crime rate trends in the United States. Since various researchers have found such trends to increase with the proportion of the population in teen and young adult years (Fox, 1976; Land and Felson, 1976; Sagi and Wellford, 1968; Wellford, 1973), we include the population ages 15–24 per 100,000 resident population in year t as our first control variable (source: USBC, various years). Others (e.g., Brenner, 1976a; 1976b) have found unemployment rates to vary directly with official crime rates over time, although this relationship elsewhere has been shown to be empirically questionable (see Mansfield et al., 1974: 463; Cohen and Felson, 1979). Thus, as our second, control variable, we take the standard annual unemployment rate (per 100 persons ages 16 and over) as a measure of the business cycle (source: BLS, 1975).

Four of the five crime rates that we utilize here (forcible rape, aggravated assault, robbery and burglary) are taken from FBI estimates of offenses per 100,000 U.S. population (as revised and reported in OMB, 1973). We exclude larceny-theft due to a major definitional change in 1960 and auto theft due to excessive multicollinearity in the analysis.⁸ For our homicide indicator we employ the

homicide mortality rate taken from the vital statistics data collected by the Bureau of the Census (various years). The latter rate has the advantage of being collected separately from the standard crime reporting system and is thought to contain less measurement error (see Bowers and Pierce, 1975). Hence, this analysis of official index crime rates includes three violent offenses (homicide, forcible rape, and aggravated assault), one property offense (burglary), and one offense which involves both the removal of property and the threat of violence (robbery). The analysis thus includes one offense thought to have relatively low reporting reliability (forcible rape), one thought to have relatively high reliability (homicide), and three others having relatively intermediate levels of reporting quality (Ennis, 1967).

Since official crime rates in year t are likely to reflect some accumulation of criminal opportunity and inclinations over several years, one should not expect these rates to respond solely to the level of the independent variables for year t . A useful model of cumulative social change in circumstances such as this is the difference equation, which can be estimated in two forms (see Goldberg, 1958). One form takes the first difference ($y_t - y_{t-1}$) as the dependent variable—in this case, the change in the official crime rate per 100,000 population between year $t-1$ and year t . Alternatively, one can estimate the difference equation in autoregressive form by taking the official crime rate in year t as a function of the exogenous predictors plus the official crime rate in year $t-1$ on the right-hand side of the equation. (See Land, 1978, for a review of these and other methods and for references to related literature.) Both forms are estimable with ordinary least squares methods, which we employ for the years 1947 through 1974. The N is 28 years for all but the homicide rate, for which publication lags reduce our N to 26.

Even if a positive relationship between the household activity ratio and the official crime rates is observed, with controls for age and unemployment, we are open to the charge that this may be a spurious consequence of autocorrelation of disturbances, that is, the possibility that residu-

⁸ The auto theft rate lagged one year correlated quite strongly with the predictor variables. This multicollinearity impaired our difference equation analysis, although we again found consistently positive coefficients for the household activity ratio. We were able to remove autocorrelation by logging all variables and including the unemployment as a control, but do not report these equations.

als are systematically related for nearby time points. While spurious relationships are a risk one also takes in cross-sectional regression analysis, time-series analysts have devised a variety of methods for monitoring and adjusting for spuriousness due to this autocorrelation, including the Durbin and Watson (1951) statistic, Durbin's *h* statistic (Durbin, 1970), the Griliches (1967) criterion, as well as Cochran and Orcutt (1949) corrections. We employ (but do not report in detail) these methods to check for the likelihood that the observed relationship is spurious. (See Land, 1978, for a review of such tests and the related literature on their applicability and robustness; see Theil, 1971, for a methodological review.)

Findings

Our time-series analysis for the years 1947–1974 consistently revealed positive and statistically significant relationships between the household activity ratio and each official crime rate change. Whichever official crime rate is employed, this finding occurs—whether we take the first difference for each crime rate as exogenous or estimate the equation in autoregressive form (with the lagged dependent variable on the right-hand side of the equation); whether we include or exclude the unemployment variable; whether we take the current scales of variables or convert them to natural log values; whether we employ the age structure variable as described or alter the ages examined (e.g., 14–24, 15–19, etc.). In short, the relationship is positive and significant in each case.

Before calculating the difference equations, we regressed each crime rate in year *t* on the three independent variables for year *t*. This ordinary structural equation also produced consistent positive and significant coefficients for the routine activity coefficient, the total variance explained ranges from 84% to 97%. However, the Durbin-Watson statistics for these equations indicated high risk of autocorrelation, which is hardly surprising since they ignore lagged effects. Reestimated equations taking first differences as endogenous reduced the risk of autocorre-

lation significantly (and also reduced variance explained to between 35% and 77%). These equations also consistently produce significant positive coefficients for the household activity variable. When unemployment is included in these equations, its coefficients are all negative and near zero.

The top panel of Table 6 presents regression estimates of first differences for five official crime rates, with the age structure and household activity variables in year *t* as the only predictors. Again, the household activity coefficients are consistently positive, with *t* ratios always significant with a one-tailed test. Except for the aggravated assault equation, the household activity variable has a *t* ratio and standardized coefficient greater than that of the age structure variable. The standardized coefficients for the household activity variable range from .42 to .72, while the age structure coefficients are consistently positive. In general, the household activity variable is a stronger predictor of official crime rate trends than the age structure.

The equations in the top panel of Table 6 generally have lower variance explained but also lower risk of autocorrelation of disturbances than those reported above. For all five equations, the Durbin-Watson statistic allows acceptance of the null hypothesis that autocorrelation is absent at the 1% level. A 5% level (which *increases* the likelihood of proving the statistic non-zero) allows us neither to accept nor reject the null hypothesis that autocorrelation is absent in the homicide and robbery equations.

Though autocorrelation has not been proven to exist in these five equations, its risk may be sufficient in two to motivate further efforts at equation estimation (see bottom panel of Table 6). We estimated the equations in autoregressive form to see if the risk abates. Since the Durbin-Watson statistic was not designed for evaluating autocorrelation in these equations, we calculated Durbin's *h*, a statistic specifically designed for equations estimated with a lagged dependent variable (Durbin, 1970), and recently found to be robust for small samples (Maddala and Rao, 1973). This statistic allows ac-

Unemployment Rate as Control,					
Effect Upon Household Activity	Minimal	Minimal	Minimal	Minimal	Minimal

ceptance of the null hypothesis (at both 1% and 5% levels) that autocorrelation is absent for all five equations. Application of the Griliches (1967) criterion further allows acceptance of each equation as manifesting distributing lags rather than serial correlation. We also employed the Cochrane-Orcutt (1949) iterative procedure to calculate a correction estimate for any autocorrelation present. The resulting correction for the household activity coefficient proves minimal in all five cases. Finally, we calculated each of the above equations for natural log values of the relevant variables, finding again that the household activity coefficient was consistently positive and statistically significant and the risk of autocorrelation reduced still further.

The positive and significant relationship between the household activity variable and the official crime rates is robust and appears to hold for both macro- and microlevel data; it explains five crime rate trends, as well as the changing composition of official crime rates reported in Table 5. These results suggest that routine activities may indeed provide the opportunity for many illegal activities to occur.

DISCUSSION

In our judgment many conventional theories of crime (the adequacy of which usually is evaluated by cross-sectional data, or no data at all) have difficulty accounting for the annual changes in crime rate trends in the post-World War II United States. These theories may prove useful in explaining crime trends during other periods, within specific communities, or in particular subgroups of the population. Longitudinal aggregate data for the United States, however, indicate that the trends for many of the presumed causal variables in these theoretical structures are in a direction opposite to those hypothesized to be the causes of crime. For example, during the decade 1960-1970, the percent of the population below the low-income level declined 44% and the unemployment rate declined 186%. Central city population as a share of the whole population declined slightly, while the

percent of foreign stock declined 0.1%, etc. (see USBC, 1975: 654, 19, 39).

On the other hand, the convergence in time and space of three elements (motivated offenders, suitable targets, and the absence of capable guardians) appears useful for understanding crime rate trends. The lack of any of these elements is sufficient to prevent the occurrence of a successful direct-contact predatory crime. The convergence in time and space of suitable targets and the absence of capable guardians can lead to large increases in crime rates without any increase or change in the structural conditions that motivate individuals to engage in crime. Presumably, had the social indicators of the variables hypothesized to be the causes of crime in conventional theories changed in the direction of favoring increased crime in the post-World War II United States, the increases in crime rates likely would have been even more staggering than those which were observed. In any event, it is our belief that criminologists have underemphasized the importance of the convergence of suitable targets and the absence of capable guardians in explaining recent increases in the crime rate. Furthermore, the effects of the convergence in time and space of these elements may be multiplicative rather than additive. That is, their convergence by a fixed percentage may produce increases in crime rates far greater than that fixed percentage, demonstrating how some relatively modest social trends can contribute to some relatively large changes in crime rate trends. The fact that logged variables improved our equations (moving Durbin-Watson values closer to "ideal" levels) lends support to the argument that such an interaction occurs.

Those few investigations of cross-sectional data which include household indicators produce results similar to ours. For example, Roncek (1975) and Choldin and Roncek (1976) report on block-level data for San Diego, Cleveland and Peoria and indicate that the proportion of a block's households which are primary individual households consistently offers the best or nearly the best predictor of a block's crime rate. This relationship persisted after they controlled for numerous

social variables, including race, density, age and poverty. Thus the association between household structure and risk of criminal victimization has been observed in individual-level and block-level cross-sectional data, as well as aggregate national time-series data.

Without denying the importance of factors motivating offenders to engage in crime, we have focused specific attention upon violations themselves and the prerequisites for their occurrence. However, the routine activity approach might in the future be applied to the analysis of offenders and their inclinations as well. For example, the structure of primary group activity may affect the likelihood that cultural transmission or social control of criminal inclinations will occur, while the structure of the community may affect the tempo of criminogenic peer group activity. We also may expect that circumstances favorable for carrying out violations contribute to criminal inclinations in the long run by rewarding these inclinations.

We further suggest that the routine activity framework may prove useful in explaining why the criminal justice system, the community and the family have appeared so ineffective in exerting social control since 1960. Substantial increases in the opportunity to carry out predatory violations may have undermined society's mechanisms for social control. For example, it may be difficult for institutions seeking to increase the certainty, celerity and severity of punishment to compete with structural changes resulting in vast increases in the certainty, celerity and value of rewards to be gained from illegal predatory acts.

It is ironic that the very factors which increase the opportunity to enjoy the benefits of life also may increase the opportunity for predatory violations. For example, automobiles provide freedom of movement to offenders as well as average citizens and offer vulnerable targets for theft. College enrollment, female labor force participation, urbanization, suburbanization, vacations and new electronic durables provide various opportunities to escape the confines of the household while they increase the risk of predatory

victimization. Indeed, the opportunity for predatory crime appears to be enmeshed in the opportunity structure for legitimate activities to such an extent that it might be very difficult to root out substantial amounts of crime without modifying much of our way of life. Rather than assuming that predatory crime is simply an indicator of social breakdown, one might take it as a byproduct of freedom and prosperity as they manifest themselves in the routine activities of everyday life.

INTERGENERATIONAL OCCUPATIONAL MOBILITY AND FERTILITY: A REASSESSMENT*

FRANK D. BEAN AND GRAY SWICEGOOD

University of Texas, Austin

American Sociological Review 1979, Vol. 44 (August):608-619

This paper examines the relationship between intergenerational occupational mobility and family size; it focuses on the partition of cumulative fertility into two components—intended and unintended births—that may respond differently to social and economic sources of influence. Four theoretical perspectives are drawn upon to set forth alternative predictions of the relationship between unintended and intended births for upwardly and downwardly mobile couples. The results of regression analyses of 1970 National Fertility Survey data lend support to Easterlin's *relative economic status* hypothesis, which advances the expectation of a positive relationship between direction of mobility and fertility, although this pattern is observed only for unintended births. The implications of this finding for certain theories of fertility, as well as for the inconclusive nature of previous research into the mobility-fertility relationship, are discussed.

Social mobility provides one of the major points of articulation between social stratification and demography. Not only is social mobility an integral feature of all systems of social stratification (e.g., Lopreato et al., 1976; Tyree and Hodge, 1978), it also has noticeable demographic correlates, both for societies and individuals (Blau and Duncan, 1967:361; Featherman and Hauser, 1978). One of the most important would seem to be fertility, as evidenced by numerous empirical studies conducted during the past 25 years (e.g., Berent, 1952; Goldberg, 1959; Tien, 1961;

Westoff, 1953; Westoff et al., 1961; Westoff et al., 1963; Boyd, 1973). The cumulative research evidence, however, has been inconclusive, if not totally negative. Scarcely any substantial basis has been found for the conclusion that social mobility accounts for additional variation in fertility above and beyond that which is associated with measures of origin and destination position themselves (e.g., Duncan, 1966; Boyd, 1973).

For the most part, explanations of these negative results, as distinct from theoretical interpretations that are consonant with the idea that knowledge of origin and destination positions suffices to explain the fertility of the mobile (e.g., Blau, 1956:29), have taken either of two tracks. On the one hand, they have suggested that the methodological basis for assessing relationships between mobility and fertility is biased against the discovery of such relationships (e.g., Hope, 1971; 1975; Lopreato et al., 1976). On the other hand, they

The data upon which this paper is based were collected pursuant to contract #PH-43-65 1048 with the National Institute of Health, Public Health Service, Department of Health, Education and Welfare. We would like to express our appreciation to Carolyn Boyd, Norval Glenn, Joseph Lopreato, Alberto Palloni, and two anonymous reviewers for helpful comments on an earlier draft of the paper.

have noted that the correlates of mobility may not be very pronounced in developed societies because the distinctions connected with social position in such societies are more diffuse and less sharply defined, thus mitigating the effects of movement across class or status boundaries (e.g., Germani, 1966; Treiman, 1970). While both of these may account for the failure to observe a relationship between mobility and fertility, another possibility is that different kinds of childbearing may respond variously to the experience of mobility. Although some students of the mobility-fertility relationship have examined both cumulative fertility and the effectiveness of fertility planning as separate (though clearly related) responses to mobility (e.g., Kantner and Kiser, 1954; Westoff et al., 1961), no studies to our knowledge have inquired into the relationship between mobility and different fertility components, thus allowing for the possibility that these might have varying motivational, social, and economic origins.

This lacuna no doubt stems from the absence until recently of attempts to partition cumulative fertility in ways that might potentially reflect such sources of influence. Cumulative fertility has both quantitative and temporal aspects. As Ryder and Westoff (1972; Westoff and Ryder, 1977; Ryder, 1978) note, completed family size may include both planned and unplanned births, the latter consisting of timing failures as well as births that the parents never intended to have. Hence, by distinguishing unplanned births according to whether or not the parents ever intended to have them, we may define an unintended birth as not only one that was unplanned, but also one that the parents never intended to have. An intended birth is one that the parents either planned at the time it was conceived or one that they would have had at some future point anyway.

The difference between intended and unintended births is crucial for present purposes because it distinguishes the desire to have children from the tendency actually to have them. In the words of Ryder and Westoff (1972:471), "The distinction . . . permits the separation of two

sources of (fertility) differentials: the demand for children and the effectiveness of fertility control." Because these conceivably may respond differently to various sources of influence, it is important to examine theories about the relationship between mobility and fertility in terms of whether the explanatory factors they emphasize might be expected to bear different relationships to these different kinds of fertility outcomes. To the extent that this is the case, estimates of the mobility-fertility relationship based on analyses that do not treat them separately may be subject to an unknown amount of distortion.

ALTERNATIVE THEORETICAL PERSPECTIVES

One of the most frequently cited theoretical perspectives invoked to predict a relationship between mobility and fertility underscores the socially disintegrative aspects of the mobility experience (e.g., Sorokin, 1927; Blau and Duncan, 1967). In this view, social mobility is seen as a process that disrupts established social ties and relationships and thrusts people into new and potentially alienating environments. Such social disequilibrium is thought either to inhibit severely the reproduction process because of accompanying strain and disorientation or to lead to high fertility as mobile couples compensate for previously lost social ties with unusually large families (Blau and Duncan, 1967:415-7; Hoffman and Wyatt, 1960).

These views, both of which may be subsumed under the disintegrative framework and which may be termed *stress and disorientation* and *social isolation*, respectively, generate predictions that run in opposite directions, not only between views but also within views by kind of fertility outcome. Although both emphasize the disruptive features of mobility, the former envisions the mobile individual as having experienced sufficient stress and strain to interfere with normal social experiences and decrease the desire for children, whereas the latter sees the mobile individual as socially isolated and disaffected and thus interested in increasing childbearing in compensation.

These views also generate opposite predictions when applied to unintended childbearing. Because strain and disorientation seem to contribute to greater contraceptive failure (Bean and Aiken, 1976), the disorientation perspective offers a basis for predicting a positive relationship between mobility and unintended fertility. By contrast, the kind of forces underlying the social isolation perspective might be expected to decrease unintended fertility because they would operate to reduce the tendency to designate births retrospectively as unintended.¹

A second general perspective, which may be termed *status enhancement*, finds expression in the work of Westoff and his associates (1953; Westoff et al., 1961). The argument here is that mobility is accompanied by reduced fertility because diminished childbearing permits gains in time, money and energy that can be devoted to attaining and/or maintaining higher social positions (in the case of the upwardly mobile) or to efforts to recapture previous positions, or perhaps attempts to avoid their further decline (in the case of the downwardly mobile). The reduced fertility seen to accompany mobility may be either intended, unintended, or both. Just as the mobile may desire fewer children in order to enhance their socioeconomic position, so may they also take greater care to avoid unintended births.

The work of Easterlin (1969; 1975; 1978) provides still another theoretical framework, as well as a different prediction. His approach, which may be termed *relative economic status*, suggests that high relative economic status will cause an increase in fertility because it decreases age at marriage and increases the pace of early marital fertility (MacDonald and Rindfuss, 1978). By relative economic status he means the ratio of permanent income (i.e., lifetime income) to consumption preferences formed in the parental household. Thus, if permanent income is high relative to tastes for consumer goods established

while growing up, fertility is expected to be high. On the assumption that the upwardly and downwardly mobile have respectively higher and lower relative economic status than the nonmobile, we would expect the upwardly mobile to show comparatively higher and the downwardly mobile comparatively lower fertility. This prediction may be stated with respect to either intended or unintended fertility (or both), depending upon whether the operative mechanism is one of raising the demand for births or one of lowering the demand for fertility regulation (or both) (Bean et al., 1978).

A final possibility concerns selectivity. Higher or lower fertility may be selective of couples who are respectively upwardly or downwardly mobile (Fisher, 1929; Blau and Duncan, 1967:368). Because children require the expenditure of resources (both tangible and intangible), couples with unusually high fertility may find it all the more difficult to maintain social positions inherited from the previous generation, while couples with very low fertility may find it all the easier to achieve social gains. Again, these predications might be expected to apply equally well to intended or unintended fertility, since either type of fertility could be selective of the particular mobility status in question.

In sum, several theoretical frameworks offer alternative bases for predicting the relationship between intergenerational occupational mobility and fertility. These are listed in Table 1, together with an indication of whether the given perspective would predict higher or lower intended and unintended fertility for upwardly and downwardly mobile couples. The primary purpose of this paper is to see which of these various theoretical perspectives provides the best prediction of the relationship between mobility and fertility. Examination of empirical relationships between intergenerational occupational mobility and intended and unintended fertility provides not only a test of alternative theories, but also a potential illustration of why the results of previous research based on undifferentiated fertility measures have yielded inconclusive evidence in support of hypotheses relating mobility and fertility.

¹ Neal and Groat (1975) observe that social isolation bears a positive relationship to unplanned fertility. Their analysis, however, does not distinguish intended and unintended births.

Table 1. Predicted Direction of Relationship between Mobility and Fertility for Alternative Theoretical Perspectives

Theoretical Perspective	Intended Births		Unintended Births	
	Up Mobility	Down Mobility	Up Mobility	Down Mobility
I. Social Disintegration				
a. Stress and Disorientation (Sorokin; Blau and Duncan)	-	-	+	+
b. Social Isolation (Blau and Duncan; Hoffman and Wyatt)	+	+	-	-
II. Status Enhancement (Westoff et al.)	-	-	-	-
III. Relative Economic Status (Easterlin)	+	-	+	-
IV. Selectivity (Fisher)	-	+	-	+

DATA AND METHODOLOGY

The different hypotheses about the relationship between mobility and fertility are assessed using data from the 1970 National Fertility Survey (NFS). This survey was a national (areal) probability sample of ever-married women born in the United States since July 1, 1925. A total of 6,752 women were interviewed, including a double quota of blacks in an effort to generate meaningful estimates of various fertility measures for this population subgroup. The principal deficiency of the sample is that it is somewhat underrepresentative of women residing in the central cities of large SMSAs (Westoff and Ryder, 1977). While this may affect the amount of occupational mobility in the sample, particularly among blacks, we do not feel that it would bias our estimate of mobility-fertility relationships for reasons to be noted below.

It is necessary to place certain restrictions on the sample for purposes of the present investigation. First, we restrict the sample to women who were far enough along in their childbearing to have been exposed to the risk of having an unintended birth. Thus, all women intending to have more children at the time of the interview are excluded. Second, since we define intergenerational mobility in terms of the current occupation of the husband and the occupation of the husband's father, we restrict the sample to women who were married at the time of the interview. Although we cannot say with certainty, we would think this would reduce

bias in the results owing to underrepresentation of central city women, since such women are less likely to be currently married (Carter and Glick, 1976:246). Third, in order to avoid the ambiguities involved in studying the fertility of women in higher order marriages, only once-married women are included; this should also reduce distortion in the findings owing to sample bias. Altogether, these delimitations yield a study sample of 2,265 respondents.

Occupational status is measured in terms of Duncan SEI scores (Duncan, 1961). While Siegel (1971) prestige scores are also available for the occupational data, these would be less useful for an analysis of occupational mobility than status scores. Because the latter are based on education and income, they provide less "error prone" estimates of the socio-economic attributes of occupations² than prestige scores (Featherman and Hauser, 1976:405). Moreover, in evaluating the Easterlin hypothesis as an interpretation of any relationship between mobility and fertility, scores derived from the educational and income characteristics of occupations would seem to provide a better proxy of permanent income than would scores based on prestige.²

² The SEI is an imperfect indicator of permanent income since it is an average of an occupation's educational level as well as its income. Some white-collar occupations with relatively modest earnings will have their SEI scores pulled up by their relatively high educational levels, while some blue-collar occupations with similar earnings but lower educa-

We assess intergenerational occupational mobility by comparing the occupational status of the respondents' husbands' fathers with the occupational status of the husbands themselves at the time of the interview. We do not use the husband's occupational status at the time of marriage on the assumption that this would not furnish as reliable an indication of eventual location in the occupational structure as a job later in the life cycle (Featherman and Hauser, 1978:88). More important, the hypotheses about the relationship between mobility and fertility do not always require that mobility be the independent variable (as in the case of the selectivity hypothesis). For all of these reasons, a measure of occupation later in the occupational life cycle seems preferable. In order to take into account differences among husbands in occupational attainment owing to variation in length of career, however, we introduce age as a control variable in all of the analyses.

Occupational mobility occurs because of intercohort changes in occupational structure as well as because of individual movements. These different kinds of mobility have been referred to as *structural* and *circulation* mobility, respectively, and efforts to separate the two in aggregate analyses of mobility tables have been numerous (Rogoff, 1953; Blau and Duncan, 1967; Tyree, 1973). This distinction needs to be kept in mind when we define mobility operationally. The initial step we take in this regard is to subtract the husbands' fathers' SEI score from the SEI score for husbands' current job. If this difference exceeds 40 SEI points, we classify the couple as upwardly mobile; if it is less than minus 20 points, we classify the couple as downwardly mobile.

This might be viewed as a somewhat extreme definition of mobility. However, it increases the likelihood that the respondents will have incurred enough status change to be of some consequence. Featherman and Hauser (1973:252-3) report average intergenerational differences

in occupational status for U.S. men in 1973 of approximately 12 points on the Duncan scale (about one-half of a standard deviation); these figures are nearly identical to the differences observed for the men in the present sample (see Table 2). The criterion for upward mobility of a difference of 40 status points, then, is equivalent to requiring that husbands in the sample be about one and two-thirds standard deviations above the SEI score of their fathers in order to be categorized as upwardly mobile. In the case of the measured mobility of any given individual, of course, we cannot speak of a portion of this owing to structural and circulation mobility respectively, because the latter are aggregate rather than individual properties. Nonetheless, it is reasonable to assume that the individual consequences of mobility may be mitigated when structural mobility is high. Moreover, the alternative theories being examined here, particularly the *stress and disorientation* and *social isolation* hypotheses, may be argued to be most adequately tested under conditions maximizing the likelihood of the individual consequences of mobility. Hence, given that a significant amount of structural mobility is characteristic of the U.S. occupational structure (Featherman and Hauser, 1978:102), the definition does not seem unreasonably stringent.

In the case of downward mobility, we have established a criterion that involves less movement along the SEI scale. This is in consideration of the average intergenerational shift upward of more than ten SEI points in occupational status. That is, given the overall preponderance of upward over downward moves, it is likely that less movement is required to be of some consequence in the case of downward as opposed to upward mobility. The adoption of these two definitions of mobility, then, result in almost 16% of the couples in the study sample being classified as upwardly mobile and more than 9% as downwardly mobile.³

tional levels will have lower SEI scores. Nonetheless, the SEI undoubtedly reflects permanent income, and it probably does so to an even greater extent than current income since the latter does not reflect adequately the lifetime earnings of younger men.

³ It should also be noted, however, that 48.6% of the couples *could not* be downwardly mobile by this definition because their fathers had SEI scores of 20 points or lower: by the same token, 17.4% *could not* be upwardly mobile. Hence, if we only consider couples who could possibly be mobile in either direc-

In the analyses which follow, we assess the relationship between upward and downward mobility and both intended and unintended fertility; we control statistically the effects of both origin and destination occupational status. We also adjust for a number of other variables that might be thought to affect the relationships. These include: wife's education, wife's age at marriage, husband's age, farm background, current farm residence, religion, race and, in the case of models involving unintended fertility, the length of exposure to the risk of an unintended birth. This latter variable is defined as the number of months since a woman had her last intended birth. Our measures of the fertility variables follow the procedures outlined by Ryder and Westoff (1972; Westoff and Ryder, 1977). In order to assess the mobility-fertility relationship, we regress the various measures of fertility on the status, control, and mobility variables; we examine first the regressions for the total number of births (intended plus unintended) and then the regressions for the number of intended and unintended births separately.

The various theoretical perspectives on the mobility-fertility relationship include hypotheses of relationships between mobility and intended or unintended fertility that run in opposite directions. They also include hypotheses of relationships that run in the same direction for upward and downward mobility, as well as predictions that run in opposite directions depending on the direction of mobility. In general, two different patterns are suggested. In one, couples who are socially mobile, irrespective of the direction of the mobility, are expected to show a level of fertility that is different from that of nonmobile couples. In the other, upwardly mobile couples are expected to manifest a fertility level that is different from that of downwardly mobile couples (irrespective of whether this differs from the level of nonmobile couples). Actually, both of these patterns could happen at the same time. In order to allow for this, the upwardly mobile, downwardly mobile and non-

mobile categories were coded in such a way as to generate a set of orthogonal contrasts reflecting these possibilities (Kerlinger and Pedhazur, 1973:145-50). That is, on the one hand, the two mobility categories were contrasted with the nonmobile category and, on the other hand, the upwardly mobile category was contrasted with the downwardly mobile category.

When appropriately coded to reflect category differences in sample size, these contrasts are statistically independent, meaning that the F-ratios associated with them in a regression analysis reflect their relative (and independent) contributions to explained variation in fertility above and beyond that associated with the effects of origin and destination status (and control variables).⁴ Thus, we estimate a regression model of the following form:

$$\hat{F} = a + b_1O + b_2D + b_3X + cZ_1 + dZ_2,$$

where F = a fertility measure (either total births, intended births, or unintended births), O = origin status (in SEI units), D = destination status (in SEI units), and X = a control variable (see Table 2 for scale units), Z_1 = a contrast-coded variable constructed to assess the mean fertility difference between the mobile and the nonmobile, and Z_2 = a contrast-coded variable constructed to assess the mean fertility difference between the upwardly and downwardly mobile. Actually, all of the control variables were entered into the model simultaneously, although we do not show this in the above equation for simplicity of presentation.

The contrast variables were coded such that a positive value of c indicates higher fertility for the mobile and a positive value

⁴ The coding procedure used to produce the orthogonal contrasts is:

Mobility	Z_1	Z_2	Proportion of Cases
Up	$-n_2$ (-16.92)	n_3 (2.14)	.158
Stable	$n_1 + n_3$ (5.73)	0	.747
Down	$-n_2$ (-16.92)	$-n_1$ (-3.59)	.094

where n_1 = frequency of upwardly mobile divided by 100,

n_2 = frequency of stable divided by 100,

n_3 = frequency of downwardly mobile divided by 100.

tion, by the above definitions, then the percentages of couples who are mobile among those who could possibly be mobile is even higher (19.2 and 18.4%, respectively, for upward and downward mobility).

^a Coded as follows: (1) grades 1-8; (2) 1-3 years high school; (3) 4 years high school; (4) 1-3 years college; (5) 4 or more years college.

^b In years.

^c In years.

^d A dummy variable indicating farm background (growing up on a farm) for either husband or wife.

^e A dummy variable indicating current farm residence.

^f A dummy variable for Catholics and Mormons.

^g A dummy variable indicating race.

of d indicates higher fertility for the upwardly mobile. Translating the predictions of the various theoretical perspectives into expectations for values of c and d , we observe that the stress and disorientation perspective would predict a negative value for c in the case of intended fertility, a positive value in the case of unintended fertility, and a zero value for d . The social isolation perspective would predict a positive value for c in the case of intended fertility, a negative value in the case of unintended fertility, and a zero value for d . The status enhancement approach would predict a negative value of c for both intended and unintended fertility and a zero value for d . The relative socioeconomic status perspective would predict a positive value for d for both intended and unintended fertility and a zero value for c , whereas the selectivity hypothesis would predict a negative value for d and a zero value for c for both fertility measures.

It should be emphasized that since Z_1 and Z_2 are a priori orthogonal contrasts and thus independent, the statistical significance of either (or both) may be taken as evidence in support of some pattern of a mobility-fertility relationship, although not necessarily one of those predicted by the aforementioned theories (Hope, 1971). Merely as a statistical yardstick this is a conservative criterion. The sizes of the mobile categories are relatively small, meaning that the contributions they can make to increasing the explained fertility sums of squares are somewhat constrained from the outset (see Jackson and Curtis, 1972). Moreover, Z_1 and Z_2 , though orthogonal to one another, are estimated on the basis of a regression model that partials out overlapping variance between the status dimensions and the interaction effects they represent. While we could adopt alternative approaches to the assessment of mobility effects (e.g., Hope, 1975), we choose the more conservative approach in view of our greater interest in comparing the different theoretical perspectives than in comparing alternative statistical approaches.

RESULTS

Table 2 presents the intercorrelations, means and standard deviations for the

variables used in the regression analyses. On the average, the women in the sample had over 2.6 intended births per woman and slightly more than 0.4 unintended births per woman. Altogether, the average number of births to women in the sample was slightly more than 3.0 per woman. The results of the regressions of the fertility measures on the control, status, and mobility variables are presented in Table 3. In the A columns are the results of regression models allowing for the additive effects of the control variables, together with those of origin and destination occupational status only, whereas in the B columns are the results of regression models allowing not only for the additive effects of the control and origin and destination variables, but also for the nonadditive effects of upward and downward mobility. The latter are presented in terms of the coefficients associated with the two orthogonal contrasts, Z_1 and Z_2 , which taken together yield an effect on fertility equivalent to that which would be obtained using dummy variables for upward and downward mobility. At the bottom of the table are F-tests for the significance of the increment to R^2 associated with the models in the B columns over those associated with the column A models.

A brief comment on the relationships between the nonmobility and the fertility variables is in order, although these are not of central interest to our concerns here. All of the relationships involving control variables are in the expected direction across fertility measures, and all are statistically significant for at least one of the fertility variables. Occupational status at origin bears no consistently discernible relationship to the fertility measures, whereas destination status exhibits a uniformly negative relationship that is statistically significant for total and unintended births though not for intended births.

Turning to the mobility results, we find that in the case of the regressions involving the total number of births, the addition of the mobility contrasts to the regression model in column A does not significantly improve the fit of the data to the model. This result is in accordance with the findings of the vast bulk of previous research, but it does not tell us if mobility bears a

different relationship to the intended and unintended components of fertility. For this, we turn to an examination of the remainder of Table 3. Although the addition of the mobility contrasts does not significantly improve the explanatory power of the regression model in the case of intended births, their inclusion clearly does so in the case of unintended births. Moreover, it is the Z₂ contrast that accounts for nearly all of the mobility effect.

The value of the coefficient associated with the contrast is positive, indicating that the upwardly mobile have higher average unintended childbearing than the downwardly mobile. In fact, extraneous of the influence of the control and status variables, the upwardly mobile reveal a level of unintended childbearing (not shown in the table) that is nearly 0.2 of a child above that of the nonmobile couples, and the downwardly mobile a level nearly 0.3 of a child below the nonmobile couples. The average difference in level of unintended fertility between the upwardly and downwardly mobile couples is nearly 0.5 of a child on the average.⁵

⁵ The significant coefficient for Z₂ may be substantially translated into a predicted net average difference in unintended births for the upwardly mobile minus the nonmobile of .18 by substituting the score on Z₂ above into the regression equation. The net average difference for the nonmobile minus the

Recalling the alternative predictions of the various theoretical perspectives, we find that the results are most consistent with the relative economic status position of Easterlin. That is, the upwardly mobile exhibit for *unintended* births a positive value of *d* and an insignificant value of *c*, indicating higher fertility for the upwardly mobile as compared with the downwardly mobile. Hence, the results lend support to the notion that higher relative economic status is associated with a rise in fertility and lower relative economic status with a decline. The appearance of this pattern *only* for unintended childbearing is consistent with the idea that the different fertility components have different social and economic origins; it is also indicative of a possible source of ambiguity in previous tests of mobility-fertility relationships. But it is a finding not predicted by any of the theoretical perspectives. The question why mobility bears a relationship to unintended but not intended fertility is addressed below.

DISCUSSION

In general, these results lend support to the relative economic status hypothesis

downwardly mobile of -.29 is similarly derived:

$$\hat{F}_u = a + b_1X + \dots + .08(2.14);$$

$$\hat{F}_d = a + b_1X + \dots + .08(-3.59).$$

that intergenerational occupational mobility varies positively with fertility. Interestingly, however, the operative mechanism does not appear to be one associated with the demand for births. Rather, it would seem to be one associated with the relaxation of the perceived need for fertility regulation. That is to say, improvements in intergenerational occupational status would appear less to make people want more children than they do to make people less diligent in the practice of effective contraception. Those experiencing intergenerational declines in status, rather than wanting fewer children, have fewer unintended births, suggesting a greater effectiveness in the practice of contraceptive regulation.

The finding that mobility is related to unintended rather than intended fertility accords well with recent evidence for the United States that secular trends in cohort fertility over the past 25 years are mostly the result of changes in patterns of unintended childbearing. For example, Ryder (1978:455) notes:

During the phase of rising fertility, popularly known as the baby boom, it is approximately correct to say that there was no change in the mean number of intended births. There was, however, a deterioration in the effectiveness with which unintended fertility was prevented, and a consequent rise in unintended births.

If we assume that unintended fertility is more susceptible than intended fertility to influence by certain social and economic conditions, as Ryder's results would seem to indicate, then perhaps studies of many kinds of social correlates of fertility behavior should concentrate on unintended childbearing. The finding of the present study that intended childbearing is relatively impervious to the additive effects of occupational status as well as the nonadditive effects of occupational mobility is certainly consistent with this position. Why this should be the case is less clear, although it does suggest that the social factors affecting intended fertility may be deeply rooted in the social structure and thus relatively enduring in their effects.

The results of this research also have implications for economic theories of fertility (e.g., Schultz, 1974), of which Easterlin's relative economic status hypoth-

esis is one variant. Economic theories have been especially useful in drawing attention to the fact that having children involves costs as well as benefits (Espenshade, 1973; Bean, 1975). They have also tended to focus on factors that, to use the economist's idiom, affect the demand for births, often under the assumption of perfect control of supply (e.g., Becker, 1960). The findings of this research, together with those of others (Ryder, 1978; Bean et al., 1978), suggest that the supply of births may be at least as subject to social and economic influence as the demand for births. Translated into policy terms, this reinforces the idea that efforts to influence societal fertility patterns are likely to be more successful if they attempt to deal with fertility regulation than if they try to change desired fertility (Bumpass and Westoff, 1970).

Finally, it is important to note that previous studies of the mobility-fertility relationship that have not been able to separate the different components of completed fertility may have been biased at the outset against finding "mobility effects." Future studies of the relationship should consider that these components may relate differently to the experience of mobility. At the same time, further research is needed to see if the pattern of results observed here may be generalized to other groups of women. To a considerable degree, the results of this study are based on older women (those not intending any more children), many of whom probably had their intended children (as well as the experience of being exposed to the risk of an unintended birth) before the full impact of the "contraceptive revolution" made its presence felt in the U.S. (Westoff and Ryder, 1977). Whether younger cohorts of women will respond similarly to the experience of social mobility remains a question for further investigation.

ETHNIC POLITICAL MOBILIZATION: THE WELSH CASE*

CHARLES C. RAGIN

Indiana University

American Sociological Review 1979, Vol. 44 (August):619-635

In this paper we present an empirical test of three perspectives on ethnic political mobilization. These are: the developmental perspective, which treats ethnicity as a persistent primordial sentiment; the reactive ethnicity perspective, according to which ethnic mobilization may result from a cultural division of labor; and the ethnic competition perspective, in which ethnic mobilization is seen as an outgrowth of the increased competition between groups over roles and resources. In the Welsh case, available historical evidence lends some support to each of these perspectives. To adjudicate between them, we analyze historical census and election data on Welsh counties. This analysis supports the ethnic competition perspective, though some support is found for the developmental perspective.

INTRODUCTION: THE RESURGENCE OF ETHNICITY

Marxists and non-Marxists alike view ethnic political mobilization as a potentially disintegrative force in the modern polity. On one hand, Nairn (1977:5), a Marxist, argues that the movement toward Celtic secession in Britain may eclipse the class struggle as the major threat to the integrity of the British political system. On the other hand, "developmentalists" (Ragin, 1977), such as Lip-

set and Rokkan (1967:1-64) and Alford (1963:309-41), also view the threat to political integration posed by ethnic mobilization as acute. In the developmental perspective ethnic mobilization contradicts the expected predominance of functional cleavages in the modern polity. If ethnic mobilization in Britain does entail a negation of the functional bases of political competition, then the growth of the Celtic nationalist movements may portend the eventual break-up of Britain. For it is unlikely that the "British" polity can withstand widespread popular support in the Celtic periphery for autonomy or outright secession.

*Direct all communications to: Charles C. Ragin; Department of Sociology; Ballantine Hall; Indiana University; Bloomington, IN 47401.

This resurgence of ethnicity is not confined to the British polity. Ethnic mobilization has become increasingly important in all polities since World War II (Said and Simmons, 1976:10). Indeed, the most common cause of state-level violence in the last three decades has not been external wars but internal ethnic conflict (Said and Simmons, 1976:16). The Celtic experience in Britain is paralleled by that of the Québécois in Canada, the Flemish in Belgium, and, to a lesser extent, the Basque in Spain. While most of these conflicts have been fueled by nationalism, purely ethnic conflicts have increased independently of the growth of ethnic nationalisms.

This increased importance of ethnic affinity is anomalous in the light of classical sociological reasoning. According to this logic, ethnicity is a "primordial sentiment" (Geertz, 1963) which should wither away in societies that undergo significant structural differentiation. Thus, ethnicity is viewed as persistent, if not aberrant, in the modern setting (cf. Parsons, 1975:53-83). This traditional view of ethnicity has been challenged recently by the proponents of two competing perspectives: the reactive ethnicity perspective (Gellner, 1969; Hechter, 1975) and the ethnic competition perspective (Deutsch, 1953; Van den Berghe, 1967; Barth, 1969; Nielsen, 1977; 1978a; 1978b; Hannan, 1978).

In the next section of this paper we outline the basic tenets of these perspectives. We show that each supports a different set of predictions concerning the social structural conditions that favor ethnic political mobilization.

THREE PERSPECTIVES ON ETHNIC MOBILIZATION

The Developmental Perspective

The reasoning behind this view of ethnicity is presented most succinctly by Lipset and Rokkan (1967:1-64). The relevance of their arguments to ethnic mobilization is apparent when combined with a general diffusionist perspective on the process of nation building (see Hechter, 1975:22-30).

Briefly, Lipset and Rokkan argue that different types of political cleavages pre-

dominate during different phases of the development of the modern polity. The different types of cleavages conform to the dimensions of Parsons's AGIL scheme in a developmental typology. In this scheme cleavages that are geographically or culturally based are superseded by functional cleavages (Lipset and Rokkan, 1967:25-6) which reflect the "interests" (Weber, 1947:122-3) of actors and groups of actors defined according to their social structural positions. This predominance of functional cleavages in the modern polity, according to Lipset and Rokkan (1967:19) was brought on by the "Industrial revolution [which] . . . in the longer run tended to cut across the value communities within the nation and to force the enfranchised citizenry to choose sides in terms of their economic interests." After the extension of universal manhood suffrage, the growing predominance of functional interests in the political arena was manifested in the uniform establishment of mass, working-class political parties in European countries (Lipset and Rokkan, 1967:21). (See also Allardt and Littunen, 1964.)

For this transition to functionally-based political cleavages to become a reality on a national scale, it is necessary for the process of structural differentiation to engulf or at least reach the various "value communities" contained within the boundaries of the nation state. This is where the diffusionist perspective complements the developmental. Hechter (1975:22-30) outlines the former as follows: In societies characterized by a more advanced, modern core and a less advanced, traditional periphery, the economic integration of the periphery with the core will reduce its cultural and social organizational distinctiveness. This homogenization of core and periphery will progress as a function of the intensity of interregional interaction: the more intense these interactions, the more quickly the periphery comes to resemble the core. Thus, the cultural traditionalisms which may serve as a basis for ethnic mobilization will survive only to the extent that the peripheral area remains outside the sphere of the national economy. If the decline of distinctive cultural traditions in the periphery accompanies

social structural differentiation and precedes the extension of the suffrage, the peripheral areas should follow the lead of core areas when the transition to mass, class-based politics is made. This should result in a nationwide predominance of functionally-based political cleavages. (See also Stokes, 1968:182–202, on the nationalization of electoral forces and Butler and Stokes, 1969:247–74.)

The Reactive Ethnicity Perspective

In contrast with the developmental perspective which argues that the cultural bases of ethnic affinity persist only in the absence of social structural differentiation, the reactive ethnicity perspective argues that structural differentiation may actually enhance the salience of ethnic distinctions. Proponents of this perspective are critical of developmentalists for assuming that the universalistic allocation of roles and resources is somehow a necessary concomitant of structural differentiation. In the reactive ethnicity perspective a particularistic allocation of roles and resources may *accompany* structural differentiation. The most desirable rewards are reserved for members of the core cultural group while members of the peripheral cultural group are assigned to inferior positions and receive inferior rewards. This "cultural division of labor" (Hechter, 1975) may occur at any level of structural differentiation.

The two main proponents of this view are Gellner (1969:147–78) and Hechter (1975:30–43). Though there are important differences between these two which should not be overlooked, their predictions for our purposes converge.

Gellner defines as his problem the conditions that enhance the relevance of cultural affinity. He argues that, in general, these conditions are associated with the uneven spread of development, particularly industrialization, over the surface of the earth. This uneven spread, according to Gellner, creates more and less advanced collectivities. Often these more and less advanced collectivities reside within the territorial boundaries of multicultural political entities, and sharp cultural differences may coincide with these

broadly defined developmental differences. If cultural and developmental differences do coincide, as is often the case, the two will tend to reinforce one another, especially in the allocation of scarce roles, rewards and resources. Gellner (1969:168) argues:

... when ... new entrants in the industrial world aren't markedly distinguishable from the older, they cannot hardly be excluded. ... This is where culture, pigmentation, etc., become important: they provide means for exclusion for the benefit of the privileged, and a means of identification, etc., for the underprivileged.

For this reason, ethnic political mobilization should be seen as the product of the exclusionary practices that accompany the uneven spread of industrialization.

Hechter is in substantial agreement with Gellner; the two diverge primarily in emphasis. Hechter's deviations from Gellner mostly reflect his application of the theory to Celtic nationalism in Britain.

One important modification of Gellner's argument by Hechter is his treatment of cultural distinctiveness. In Gellner's framework, cultural distinctiveness must be sharp; otherwise, those members of the less advanced group who experience exclusion will simply forego their distinctive cultural practices in favor of assimilation. In Hechter's framework, however, relatively subtle cultural markers (e.g., accent; see Hechter, 1975:43) may serve as a basis for exclusion. A related modification is that exclusionary practices in Hechter's scheme may result in only a partial coincidence of economic and cultural subordination. This partial coincidence seems probable in a situation where markers are subtle, which presumably is the case in Celtic Britain. Finally, Hechter de-emphasizes the temporal association of ethnic mobilization with industrialization. In Gellner's argument, industrialization intensifies ethnic sentiment if assimilation does not soon follow. Hechter (1975:298–310), however, argues that the potential for ethnic mobilization may remain dormant for decades following industrialization, to be sparked only by specific political and economic factors.

Hechter buttresses Gellner's arguments with classical Marxist arguments and an

internal colonialism perspective. In Hechter's formulation a cultural division of labor is most likely when a peripheral area is developed as an internal colony. The nature of the development of the peripheral, internal colony is determined by the needs of the core developer. In the Celtic peripheral areas of Britain the specialized dependent mode of development has been industrial (Hechter, 1975; Ragin, 1977), but the industries that have been developed constitute mere appendages of the core, English economy. These dependent industries include mining and other extractive industries as well as metallurgical and other heavy manufacturing industries.¹ This pattern of industrial, internal colonial development, according to Hechter, has led to the creation of a Celtic industrial working class dominated by English or anglicized middle and upper classes.

The Marxist slant of Hechter's reactive ethnicity perspective is evident in his discussion of the structural conditions that generate and maintain ethnic affinity and of the circumstances which may spark ethnic mobilization. Generally, the structural conditions described by Hechter (1975:42) as conducive to ethnic solidarity parallel those described by Marx (1852) and Marx and Engels (1848) as conducive to class solidarity. These include (1) substantial economic inequality, (2) the perception of this inequality as part of a pattern of collective oppression, and (3) adequate communication among members of the oppressed group (Hechter, 1975:42). Hechter adds to the Marxian framework the stipulation that when cultural distinctions coincide with class distinctions, the result is ethnic (actually, ethnic-class) solidarity as opposed to class solidarity. With respect to the conditions that generate ethnic mobilization, Hechter emphasizes the disillusionment of Celtic industrial

workers with British national working-class organizations:

The years of depression in Scotland and Wales have begun to erode the strong class-conscious links of the peripheral working class to [British] national institutions. . . . [The Labour party] can no longer be counted on to protect their jobs, because, in large measure, traditional employment in heavy industries has gradually disappeared. (Hechter, 1975:309).

At the heart of ethnic affinity and ethnic mobilization, therefore, according to Hechter, are the structural and circumstantial conditions of working-class solidarity and action.²

The Ethnic Competition Perspective

Among the proponents of this perspective (Deutsch, 1953; Van den Berghe, 1967; Barth, 1969; Nielsen, 1977; 1978a; 1973b; Hannan, 1979), a common theme is that ethnic mobilization is a consequence of the competition between groups for roles and resources. In this perspective ethnic relations are likely to be stable when ethnic groups in a polyethnic situation occupy distinct structural positions in a functional division of labor (i.e., when there is a cultural division of labor) or when ethnic groups are territorially separate (Barth, 1969:9-38). A stable ethnic situation, however, may be disrupted by economic changes if these changes cause formerly separate but interdependent ethnic groups to compete for the same rewards and resources.

Hannan (1979), following Barth (1969), links ethnic identity and action to ecological processes and constraints. Specifically, he argues that economic and political modernization affects ethnicity in two, apparently contradictory ways.

(1) *Modernization reduces ethnic diversity.* Hannan's argument here is consistent with developmental logic (see above), except that his formulation is strictly ecolog-

¹ Censuses of population, particularly those of the late nineteenth century and first half of the twentieth century, consistently show the overrepresentation of these industries in the occupational composition of Wales and Scotland relative to England. The overrepresentation of these industries accounts in part for the slower rates of economic growth and the higher rates of unemployment in these areas (Hechter, 1975:298-310; Thomas, 1962:55-71).

² Hechter (1975:308), for example, makes much of the fact that the first Plaid Cymru election victory occurred in one of the more industrial constituencies (Carmarthenshire). He fails to follow this up, however, with statistical analyses of areal variations in Plaid Cymru voting.

ical. In a nutshell, he argues that modernization "joins the fate of previously unconnected populations" (Hannan, 1979:24). This connecting process undermines the ecological bases of ethnic diversity and erodes small-scale, ecologically bound ethnic identities.

(2) *Modernization increases the likelihood of large-scale ethnic political mobilization.* This second consequence of economic and political modernization follows more directly the logic of competition and selection: as subsystems within a larger system (e.g., a nation-state) become more connected and the size of the interacting population increases, the conditions of organization and competition are altered. Specifically, because the size and strength of the largest competitor (i.e., the core or center) increases, attempts at organized resistance to the core will be more successful if they are organized around large-scale identities (Hannan, 1979:31). Assuming individuals possess multiple cultural identities of varying scale or generality, the larger the population attached to a given cultural identity, the more likely it is that the identity will be used successfully as a basis for mobilization. In short, selection processes are altered by modernization such that large scale cultural identities, if available, are favored.

The predictions of the ethnic competition perspective concerning the conditions which generate ethnic mobilization differ dramatically from those of the reactive ethnicity perspective. According to the latter, ethnic mobilization may supplant class mobilization given the failure of class mobilization to provoke the core to stymie the relative economic decline of the periphery. Deteriorating economic conditions in the periphery cause the disillusionment of periphery workers with polity-wide working-class organizations. According to the ethnic competition perspective, however, it is the creation of new competitive opportunities that provokes ethnic mobilization. The disruption of a separate but interdependent status of ethnic groups should lead to ethnic competition and mobilization. This is most likely when new competitive opportunities are introduced (e.g., by economic diversification). Thus, given the

availability of large-scale cultural identities and the introduction of new economic rewards or resources, ethnic mobilization is likely.

WELSH ETHNICITY

There is considerable evidence that many of the structural conditions described by Hechter and Gellner obtained in Wales. A cultural division of labor was clearly in evidence in preindustrial, traditional Wales. During this period Wales was dominated by an anglicized (and Anglican) aristocratic society that included landlords, their farm managers and the representatives of the Church of England (Cox, 1970:127-34; Hechter, 1975:79-123). These English-speaking elites dominated a Nonconformist, Welsh-speaking tenantry. Wales was represented in Parliament by this Anglicized, landlord class, and these same landlords dominated local judicial and political functions (Cox, 1970:133).

"The nineteenth century produced a massive industrial exploitation of Wales" (Philip, 1975:2). There were great shifts of population from agrarian North Wales to the industrial South. "Between 1815 and 1914 the population of Wales rose fourfold, more so in Glamorgan and Monmouthshire [in South Wales] which together contained by 1914 over 60 percent of the entire population of Wales" (Philip, 1975:3). In Table 1 we show this explosion of population and industry in South Wales with data from seven censuses of population. We contrast the two most populous counties of South Wales (Glamorgan and Monmouthshire) with three agrarian counties of North Wales (Anglesey, Caernarvon and Merioneth). The dynamic character of the South Wales economy is illustrated by the rapid population growth rate maintained over this period and by the gradual and continual decline in percentage employed in agriculture. The slow relative growth of the population of the three North Wales counties (some decades registered an absolute decline in population) and the continued importance of agriculture testify to the economic stagnation of the North.

The influx of uprooted Welshmen in

Table 1. Selected Social Indicators for Two South Wales and Three North Wales Counties, 1851-1911

Year	South Wales		North Wales	
	Decennial Population Growth Rate	% Employed in Agriculture	Decennial Population Growth Rate	% Employed in Agriculture
1851	1.26	22	1.07	47
1861	1.24	18	1.00	50
1871	1.19	13	1.05	41
1881	1.17	11	1.07	44
1891	1.26	8	.98	48
1901	1.21	7	1.03	34
1911	1.32	5	.98	39

South Wales often resulted in the conditions favorable to ethnic consciousness cited by Gellner and Hechter. D. Williams (1950:246) argues that:

The ironmasters, many of whom had their origins in English middle class Dissent, became allied through marriage, and association with the gentry, and adopted their Anglicanism. Seldom did the Welsh workmen attain to high administrative posts. "In the works," says a government investigator in 1847, "the Welsh workman never finds his way into the office. He never becomes either clerk or agent. He may become an overseer or contractor, but this does not take him out of the labouring and put him into the administering class."

(See also G. Williams, 1971:11.) Acrimonious industrial relations tended to coincide with this culturally-based division of labor. Morgan (1970:254) notes, for example, that industrial strife was common in the eastern part of the South Wales industrial belt where there is evidence of a cultural division of labor. (See also Cox, 1970:137-8.) Industrial relations in the western portion of this belt did not sour until the late 1800s and early 1900s as the ownership of the mines became concentrated in the hands of a few outsiders (Cox, 1970:143-9; Evans, 1961:137-45), and the failure of the sliding scale (which linked wages to the market price of coal) destroyed the community of interests of workers, managers and owners (Brennan et al., 1954:139-54).

According to the logic of the reactive ethnicity perspective, the conditions cited above increase the salience of class and ethnic solidarity. To the extent that a cultural division of labor accompanied these industrial developments, Welsh ethnic affinity was maintained and enhanced by the industrialization of South Wales.

Whatever the fate of ethnic *affinity* in South Wales, the empirical evidence shows that a secular decline in cultural distinctiveness accompanied industrialization. Hechter (1975:182) comments that most of Wales was Welsh speaking in the year 1800. By 1891, however, the proportion of Welsh speakers in Wales had declined to .544, and between 1911 and 1971 the proportion declined from .350 to .196 (Morgan, 1970:315; Great Britain Office of Population Census and Surveys, 1971:132). The evidence on Welsh monoglots is even more striking. Between 1911 and 1971 the proportion of Welsh monoglots declined by a factor of 6.5, from .085 to .013 (Great Britain Office of Population Census and Surveys, 1971:132).

To what extent was this decline due to the industrialization of Wales? The available evidence shows that over time, Welsh speaking has become more and more concentrated in the least industrialized areas of Wales. In Table 2 we show the unstandardized regression coefficients from the regression of percentage of Welsh speakers on percentage employed in manufacturing occupation at five points in time from 1921 to 1971. These coefficients increase in magnitude over time from -.74 in 1921 to -1.49 in 1971. The correlations between these two measures over the same period range from -.54 in 1921 to -.69 in 1961. (See Table 2.) This pattern suggests a concentration of Welsh speakers in rural, agricultural areas where distinct cultural practices were sheltered from the onslaught of industrialization.

Despite this clear erosion of traditional Welsh culture, 69% of the Wales resident population continue to identify themselves as Welsh as opposed to British (15%) or English (13%). (See Philip,

Table 2. Regression of Percentage of Welsh Speakers on Percentage of Manufacturing Employees, 1921-1971

1975:131.) Furthermore, there are only slight areal variations in the extent to which the residents of Wales claim this ethnic label: the percentages range from about 65% in industrial South Wales to about 70% in the more traditional North Wales (Philip, 1975:132). The fact that Welsh ethnic identity is more widespread than the practice of Welsh traditionalisms (e.g., Welsh speaking) suggests that ethnic political mobilization based on ethnic culture may find only limited success. We turn now to an examination of political expressions of Welsh ethnicity in the light of this reasoning.

POLITICAL EXPRESSIONS OF WELSH ETHNICITY

There have been flurries of Welsh ethnic mobilization for over a century; these have mostly taken the form of political agitation for a Wales independent from England. The present Welsh nationalist party, the Plaid Cymru, was antedated in 1886 by the Cymru Fydd or Young Wales movement. This movement was founded by South Wales Liberals, mostly middle-class Nonconformists, who sought greater recognition of unique Welsh problems by the national Liberal party, especially before Parliament. The movement expanded rapidly in the early 1890s in both North and South Wales; eventually it came to be

dominated by the more Welsh-traditional North Wales Liberal Association.

Though the Cymru Fydd movement collapsed after only a few years of activity, Liberals in Wales continued to voice Welsh national interests. Liberal party M.P.s sponsored several home-rule measures before Parliament throughout the pre-World War I and interwar periods. It was not until the virtually total eclipse of the Liberal party by Labour in Wales that serious Liberal agitation for home-rule for Wales declined. Throughout the period of agitation, the Liberal appeal to the Welsh was strongly cultural, emphasizing the distinctiveness of Welsh Nonconformity and the Welsh language. Even though the Plaid Cymru recently has usurped the Liberal party as the voice of Welsh nationalism, many Liberal candidates continue to describe themselves as "liberal and [Welsh] national" (Madgwick et al., 1973:45-65).

At its outset, the modern Welsh national party, the Plaid Cymru, was also somewhat cultural in orientation, basing its appeal on the endangered condition of the Welsh language. Established in 1925, long after the collapse of the Cymru Fydd, the party established three goals: (1) to make the Welsh language the only official language of Wales, (2) to require all public servants in Wales to conduct their affairs in Welsh, and (3) to establish the Welsh language as the medium of education in Wales. More recently, however, the Plaid Cymru has begun to emphasize economic issues. The Plaid Cymru formulated the first national economic plan for Wales and, since 1966, has made a concerted effort to convince Welsh voters of the economic benefits that will follow from self-government. Despite this new concern for economic issues, the Plaid continues to stress cultural issues, particularly those surrounding the waning Welsh tongue.

There is fragmentary evidence that the uneven erosion of Welsh culture has presented obstacles to ethnic political mobilization. As mentioned above, the Liberal party has always maintained a strongly cultural appeal, stressing its links with Welsh Nonconformity. The Liberal party's strongly cultural stance accounts,

in part, for its quick demise following working-class mobilization by the Labour party during the interwar period. The *Cymru Fydd* (Young Wales movement) foundered on the incompatibility of the "cosmopolitan" interests of the industrial South and the cultural interests of the traditional North (Ragin and Davies, 1978). (A contemporary observer, for example, commented that "the cosmopolitan population of the great towns of South Wales will never submit to the domination of Welsh ideas" [see G. Evans, 1973:47; Morgan, 1970:163].) The fate of the *Plaid Cymru*, perhaps until recently, has been similar. It was not until the *Plaid Cymru* supplemented its cultural stance with economic positions in the late 1960s that the *Plaid* attracted strong support outside of Welsh-speaking areas (Philip, 1975:117-8).

The empirical evidence suggests that this tendency to emphasize cultural issues has restricted the appeal of Welsh ethnicity as a basis for political mobilization. Table 3 shows the correspondence between support for the two parties most sensitive to Welsh interests and an indicator of Welsh cultural traditionalism, the percentage of Nonconformist marriages. The zero-order correlations of Liberal support with Nonconformity range between .755 in 1950 and .277 in 1974, while the correlations of *Plaid Cymru* support with Nonconformity range between .436 in 1950 and .917 in 1966.³ These bivariate analyses, of course, present a one-sided view of the social bases of Welsh ethnic political mobilization; they underscore, however, the link between the cultural tone of Welsh national appeals and the relatively limited success of these appeals outside of Welsh cultural strongholds.

HYPOTHESES

The strong correlations between Welsh cultural traditionalism and ethnic political mobilization shown above suggest a pattern consistent with the developmental

Table 3. Correlations of Liberal and National Support with Nonconformity, 1935-1974

Year	Liberal Support	Nationalist Support
1935	.497	*
1945	.732	*
1950	.755	.436

1970	.515	.796
1974	.277	.825

* Nationalist support negligible.

perspective. According to the logic of this perspective, ethnic political mobilization in an advanced society results from the possible residues of peripheral cultural traditionalism which may exist in the least developed areas of a periphery. A combination of cultural persistence and relative economic isolation from the core (i.e., underdevelopment) in this perspective, provides a favorable setting for culturally-based opposition to the core: the less developed an area, the greater the salience of cultural traditionalism and the greater the likelihood of ethnic mobilization.

According to the reactive ethnicity perspective, however, ethnic identity is enhanced by the cultural division of labor which is often associated with dependent, internal colonial development. Dependent industrial development should be particularly conducive to ethnic mobilization because the conditions that enhance class solidarity are thought also to enhance ethnic solidarity. Thus, according to this perspective, those areas of the periphery which have experienced dependent industrial development should be most responsive to an ethnic appeal. Furthermore, the fact that the Labour party has failed to prevent the decline of heavy industry in Wales increases the likelihood that ethnic mobilization should supersede class mobilization.

The ethnic competition perspective predicts that ethnic political mobilization is most likely in those areas of Wales where economic diversification has occurred, not in those areas dominated by the stagnant industrial appendages of the

³ Essentially identical results are obtained when the percentage of Welsh speakers is used as an indicator of cultural persistence instead of the percentage of Nonconformist marriages. The cross-sectional correlations between these two measures are about .90.

core English economy. No longer is the entire Welsh economy dominated by mining and heavy manufacturing. The tertiary sector has expanded, and new, more advanced industries have been established (Thomas, 1962:30-49). In such sectors it is less practical to implement a cultural division of labor because of a greater diversity of tasks and a lower level of labor intensity. In general, because competition for new roles and resources is more intense in areas of economic diversification, an ethnic appeal is likely to be much more successful. Ethnic competition, and therefore mobilization, is less likely in less developed areas or in areas where a cultural division of labor is prevalent.

None of the arguments outlined above would deny that ethnic political mobilization should be high in areas where Welsh cultural traditionalisms have persisted. Because all attempts at ethnic mobilization, in varying degrees, have emphasized Welsh culture, it follows logically that the most culturally Welsh areas should be most responsive to these appeals. In Table 2 we showed the relationship between the percentage of Welsh speakers, an indicator of Welsh cultural traditionalism, and the percentage employed in manufacturing occupations. While these correlations are all negative, they show that the association between these two measures is far from perfect. In fact, though Welsh cultural traditionalism tends to be high in the least developed (i.e., agricultural) areas, some of the more industrial areas and some of the areas of economic diversification also show sizeable proportions of Welsh speakers and of Nonconformist marriages (both indicators of Welsh cultural traditionalism). Given that there is an imperfect fit between economic conditions and the cultural bases of ethnic political mobilization in Wales, it is necessary to test for the possibility that the theoretically specified structural preconditions outlined above may result in ethnic mobilization only within an appropriate cultural context. In other words, because cultural persistence seems to be an important factor as far as ethnic mobilization is concerned, it is necessary to assess the effect of structural factors on

Figure 1. Generic Models Appropriate for Assessing the Social Structural and Cultural Bases of Ethnic Mobilization

the success of the ethnic appeal *relative to* variation in cultural context.⁴

In Figure 1(a) we show the generic model for this kind of assessment. In this model variation in ethnic mobilization (M) is seen as a function of variation in the strength of the cultural bases for ethnicity (C) and social structural conditions (S_1). Additionally, the degree to which particular social structural conditions provoke ethnic mobilization is modified by cultural context. Thus, cultural and economic factors may influence ethnic mobilization directly and additively, or they may be joint preconditions for the activation of ethnic political mobilization.

The specific social structural conditions that favor a greater activation of ethnicity, of course, vary from theory to theory. The developmental perspective argues that the activation of ethnicity should be greatest in the least modernized areas of the periphery; the ethnic competition perspective argues that activation should be greatest in the most modernized and diversified areas, while the reactive ethnicity perspective argues that activation should be greatest where dependent industries predominate.

⁴ Note that none of the perspectives outlined above explicitly specifies an interactive formulation. However, the interactive model we propose does not violate the arguments of the theoretical perspectives we examine; in fact, this formulation provides a more stringent test of each perspective.

In Figure 1(b) we show a simpler model applicable to those cases (e.g., Flemish areas of Belgium) in which there are no extreme variations in the cultural bases for ethnic mobilization. Since C is a constant in this latter case, the interaction model (a) reduces to the simple additive model (b) in which mobilization is an additive function of social structural conditions.

Finally, it should be noted that different patterns of results may obtain in the analyses of the support for the two Welsh sympathetic parties. Ethnic political mobilization via Liberal party support predated class mobilization and serious Labour party contention for the control of the British state. In Wales, Labour mobilization virtually extinguished support for the Liberal party in many areas. This pattern is consistent with the developmental argument that class alignments based on "interests" supersede cleavages between "value communities" (Lipset and Rokkan, 1967:21). Because the experience of the Liberal party in Wales follows closely the historical argument of the developmental perspective, it is possible that the results from the analyses of liberal voting will contradict the results from the analyses of Plaid Cymru voting. Of course, the analysis of Plaid Cymru support is a more crucial test of the three perspectives because the most important question is one of ethnic resurgence. Thus, a pattern of results from the analysis of Liberal support consistent with the developmental perspective does not necessarily falsify the arguments of the other two perspectives because they are more concerned with resurgent ethnicity as indicated by Plaid Cymru support.⁵

DATA AND MEASURES

The measures used in this study are based on data from the *County Reports* of the *Census of England and Wales* for the years 1931, 1951, 1961 and 1971, from *Parliamentary Election Results* (1918 to 1945 and 1950 to 1970) compiled by F. W. S.

⁵ Furthermore, support for the developmental perspective from the analyses of Liberal voting also verifies the competition perspective. See discussion section below.

Craig, and from the *Annual Reports* of the Registrar of Births, Deaths and Marriages. The 1974 election results were taken from Butler and Kavanaugh (1975). The constituency election results were aggregated into county data to conform to the census data. To match the census data to the election data we interpolated and extrapolated the decennial census data to conform to election dates. We analyze the results of the elections of 1935, 1945, 1950, 1955, 1959, 1964, 1966, 1970, and 1974. The election of 1935 was selected as the starting point because it marks the beginning of "the third period in modern British politics, the period of Labour-Conservative predominance" (Kinnear, 1968:52). "After the election of 1935 there were far fewer anomalies of the sort which had marked the elections of the 1920s, and most seats were won or lost on a fairly predictable basis, related to their social composition" (Kinnear, 1968:52). With these data we constructed two dependent variables and four independent variables.

The dependent variables are measures of ethnic political mobilization. They are (1) percentage of electors voting for the Liberal party (*Liberal support*) and (2) the percentage of electors voting for the Plaid Cymru, the Welsh nationalist party (*Nationalist support*). Liberal party support was chosen because the party, in effect, has been a Welsh nationalist party since 1868 (Morgan, 1970:28-75). (See above.) Home rule for Wales has often been the policy of the Liberal party in Wales, and it has sponsored many home-rule measures in Parliament. Support for the Plaid Cymru is a more obvious measure of ethnic mobilization; this party advocates Welsh separatism, a position too extreme for the Liberal party since the latter seeks the support of voters throughout the British polity.

To measure the variation in the cultural bases for ethnic mobilization, we use a single measure, strength of Nonconformists as indicated by the percentage of Nonconformist marriages. This measure has been used by Ragin (1977) and by Hechter (1975) who gives a detailed justification for the measure. It is preferable to a linguistic measure such as the percentage of Welsh speakers because of the de-

cline in Welsh speaking over the period of observation (see above and Hechter, 1975:167-91).

The other three independent variables are measures of structural conduciveness as specified by the three perspectives discussed above.

According to the developmental perspective the ethnic appeal should be most successful in the least modernized areas since modernization implies a universalistic allocation of roles and resources and a consequent decline in the relevance of ethnicity. The traditional Welsh economy is agricultural. To measure modernization negatively, therefore, we use the percentage of adult males employed in agriculture. According to developmental logic, as the percentage in agriculture increases, the potential for ethnic mobilization should also increase.

According to the logic of the reactive ethnicity perspective, a predominance of dependent periphery industries of the sort described above (e.g., mining) should enhance the viability of the ethnic appeal. In such industries a cultural division of labor is most likely; consequently, ethnic solidarity should be greatest. To measure the prevalence of these structural conditions we use the percentage of adult males employed in mining, metallurgical and other heavy manufacturing industries.

As an indicator of the prevalence of the conditions conducive to ethnic competition we use the percentage of the adult males employed in the tertiary sector and in advanced industries. According to the ethnic competition perspective, in the most modernized sectors of the economy ethnic competition creates conditions favorable to ethnic mobilization.

METHODS AND ANALYSIS

The generic model depicted in Figure 1(a) is a conduciveness interaction model of the sort described by Southwood (1978:1154-203) and implemented by Chirot and Ragin (1975:435-41). Briefly, this model allows the strength of the relationship between the structural bases for ethnic mobilization (S) and the actual mobilization of ethnicity (M) to vary as a function of cultural context (C).

Additionally, cultural context may have a direct, additive effect on mobilization. The model can also be described with the following equation:

$$M = A_0 + (B_0 + B_1C)S + A_1C + E;$$

expanded:

$$M = A_0 + B_0S + B_1CS + A_1C + E,$$

where:

- M = degree of ethnic mobilization,
- A₀ = regression constant,
- B₀, B₁, A₁ = unstandardized regression coefficients,
- C = strength of cultural basis for ethnicity,
- S = theoretically specified social structural condition,
- CS = multiplicative interaction of C and S.

The above equation has the familiar form of the multivariate regression with a multiplicative interaction term. In the analysis below we compute this equation with the two dependent variables (Liberal support and Nationalist support) in both additive and interactive formulations. We vary the S term according to the specifications of each of the three theories.

We use the technique of pooled cross-sections in these analyses to take into account the stable but particularistic characteristics of each of the counties included in the statistical analysis (see Hannan and Young, 1977:52-83).⁶ We model these case-specific disturbances with 12 dichotomous variables since there are 13 counties. We also attempt to control for period specific disturbances which affect the computation of the intercept by including dichotomously coded variables for each of the elections. Thus, in the analyses of Liberal support we include 12 dichotomously coded county variables and eight dichotomously coded election variables in the analysis of nine pooled cross-sectional analyses (the elections of

⁶ We use the method of pooled cross-sectional analysis to increase our total number of observations and thereby allow the use of multivariate techniques for the analysis of the effects of several independent variables simultaneously.

1935, 1945, 1950, 1955, 1959, 1964, 1966, 1970, 1974). In the analyses of Nationalist support we include the 12 dichotomously coded county variables and six dichotomously coded election variables in the analysis of seven pooled cross-sectional analyses (the elections of 1950, 1955, 1959, 1964, 1966, 1970, 1974).⁷

Twelve separate regression equations were computed as follows:

A. Test of Developmental Perspective

1. Additive:

$$L \text{ or } W = a + b_1C_1 + c_1T_1 + d_1A + d_2N + e.$$

2. Interactive:

$$L \text{ or } W = a + b_1C_1 + c_1T_1 + d_1A + d_2N + d_3AN + e.$$

B. Test of Reactive Ethnicity Perspective

1. Additive:

$$L \text{ or } W = a + b_1C_1 + c_1T_1 + d_1P + d_2N + e.$$

2. Interactive:

$$L \text{ or } W = a + b_1C_1 + c_1T_1 + d_1P + d_2N + d_3PN + e.$$

C. Test of Ethnic Competition Perspective

1. Additive:

$$L \text{ or } W = a + b_1C_1 + c_1T_1 + d_1M + d_2N + e.$$

2. Interactive:

$$L \text{ or } W = a + b_1C_1 + c_1T_1 + d_1M + d_2N + d_3MN + e,$$

where,

L = Liberal support,

W = Nationalist support,

a = regression constant,

b_1, c_1, d_1, d_2, d_3 = unstandardized regression coefficients,

C_1 = dichotomously coded county variables (12),

T_1 = dichotomously coded election variables (eight or six),

A = percentage employed in agriculture,

N = percentage of Nonconformist marriages,

P = percentage employed in periphery industries,

M = percentage employed in "modern" economic sectors,

AN, PN, MN = multiplicative interaction terms,

e = error term.

The results of these analyses are reported in Tables 4 (Liberal support) and 5 (Nationalist support). The analyses reported in Table 4 are based on nine pooled cross-sections of 13 Welsh counties. The total number of observations is 117. The county data in the statistical analyses were weighted by population, but the number of degrees of freedom for significance testing purposes was set at 117. The analyses reported in Table 5 are based on seven pooled cross-sections of 13 Welsh counties, resulting in 91 observations. The county data in these analyses also were weighted by population; the number of degrees of freedom was set at 91, in line with the true number of observations.

The results of the analyses of Liberal support (Table 4) provide strongest support for the developmental perspective. The additive equations (A1, B1 and C1) show that the structural condition most favorable to Liberal support is a predominance of employment in agriculture. The structural condition least favorable to Liberal support is a predominance of employment in periphery industries. Thus, when structural conditions most conducive to class mobilization (a predominance of periphery industries) are present, ethnic mobilization, as indicated by Liberal support, is lowest; when conditions least conducive to class mobilization are present (a predominance of agricultural employment) ethnic mobilization is greatest. Further, to the extent that a predominance of agricultural employment indicates a relative isolation from the national economy, the lower the level of

⁷ The dichotomously coded variables also correct for the autocorrelation (Hanushek and Jackson, 1977), often problematic in pooled cross-sectional analyses. Suspecting heteroskedasticity, we reran the analysis with a WLS technique outlined by Glejser (1969). No significant or important differences were obtained with this technique.

integration with the national economy, the greater the level of ethnic mobilization.

The examination of equations A2, B2 and C2, which include interaction effects, does not contradict this conclusion. A significant R-square increment is obtained

only in equation C2. The coefficients reported for C2 indicate that the greater the persistence of Welsh cultural traditions, the more negative the effect of employment in the tertiary and advanced industries on Liberal support. Alternatively,

they could indicate that the greater the employment in the tertiary and advanced industries, the weaker the positive effect of cultural persistence on Liberal support. Both interpretations are consistent with developmental logic.⁸

The results of the analysis of Nationalist support reported in Table 5, however, do not support the developmental argument; they support instead the ethnic competition perspective. Equations A1, B1 and C1 show that the only structural condition that increases Nationalist support is a high level of employment in tertiary and advanced industries (M). These, presumably, are the most modern sectors of the economy, where competition is greatest. High employment in agriculture or in periphery industries does not increase nationalist support; the coefficients for A in equation A1 and P in equation B1 are both nonsignificant. Thus, neither the developmental nor the reactive ethnicity perspective is supported.

The results of the analyses with interaction terms show a significant contribution to the explained variance in each equation. However, the signs of the coefficients associated with the interaction terms are in the wrong direction in equations A2 and B2. The developmental perspective predicts that the combined effect of a high level of employment in agriculture and cultural persistence should be to increase the salience of ethnicity; in fact, the effect is to reduce its salience, as far as Nationalist support is concerned. The reactive ethnicity perspective predicts that where high employment in periphery industries and cultural persistence coincide, the likelihood of ethnic mobilization is greatest; again, the coefficient associated with this interaction term is negative, indicating that their joint effect is negative.

⁸ One could invert this logic still another way and argue that the larger the non-Welsh-speaking population, the more positive the effect of tertiary employment on Liberal support. This interpretation would contradict, however, the known correspondence between Welsh traditionalism and Liberal support. In any event the proportion of explained variation attached to this equation (Table 4, C2) is smaller than those attached to equations A1 and B1 which support, in a much simpler way, the developmental perspective.

The interaction of employment in tertiary and advanced industries with our indicator of cultural persistence, the percentage of Nonconformist marriages, however, shows that their joint effect is positive, indicating that where cultural persistence and employment in the most modern economic sectors coincide, the likelihood of ethnic mobilization is greatest. The coefficient for this term is positive and significant. This supports the ethnic competition perspective.

DISCUSSION: THE HISTORICAL CONTEXT OF ETHNIC POLITICAL MOBILIZATION

The analyses of Liberal support confirm the predictions of the developmental perspective, while the analyses of Nationalist support confirm the predictions of the ethnic competition perspective. While this may appear contradictory, the findings can be reconciled when viewed in historical perspective.

The Liberal party historically has been the national party of Wales. In its heyday the central tenets of Liberal party philosophy (e.g., Nonconformity, tolerance; individualism) coincided very neatly with those of Welsh culture (Philip, 1975:303-12). The integration of the Welsh into the British polity via Liberalism was disrupted by class politics, in general, and by the Labour party, in particular. Labour usurped the Liberals in the industrial and mining areas of South Wales. The Labour party became entrenched in industrial Wales during the interwar period, and after World War II Labour was dominant in virtually all areas of Wales, winning, for example, 32 of the 36 Welsh seats in Parliament in the election of 1966. (The Liberals won only a single seat in this election.) Liberal support was gradually confined to the least industrial (i.e., most agricultural) areas of Wales during this period. This pattern, the gradual erosion of the support for a party making a cultural appeal, follows precisely the historical argument of the developmental perspective. Lipset and Rokkan would argue that the effect of class politics in Wales was to divide and erode a value community and to magnify the importance of economic interests.

The Plaid Cymru, on the other hand, is

a creature of the modern era. The party grew as the Welsh economy diversified during the post-World War II period; the biggest increase in the party's strength occurred between the elections of 1966 and 1970 when the ratio of Welsh unemployment to unemployment in Great Britain as a whole decreased from 1.75 to 1.45 (Great Britain Central Statistical Office, 1975:35). The Nationalists gather most support in areas that are neither heavily industrial nor agricultural. This suggests that, on one hand, is it not the party of a threatened cultural minority, nor on the other, is it the party of an ethnic-class conscious industrial proletariat. Rather, the *Plaid Cymru* attempts to be the truly Welsh party of modern Wales, combining a cultural appeal and a Welsh-national economic appeal. Philip (1975:312) argues that even though the Liberals and the Welsh Nationalist "share many of the same cultural ideals," they differ "in the extent of their tolerance and radicalism." Thus the Liberals allow themselves to appear as a relatively conservative party, a Welsh alternative to the British Conservative party, while the Nationalists tend to attract those who are more strident in their Welshness. This, in part, explains the pattern of results shown above. In more agricultural areas Welsh political mobilization takes on a more conservative character via Liberalism, while in those areas that are neither heavily industrial nor agricultural it takes on a more strident character via *Plaid Cymru* support. Neither party does well in the most heavily industrialized areas of Wales. The hold of the Labour party and class politics on these areas appears to be absolute.

Evidence concerning the composition of the membership of the *Plaid Cymru* also supports the ethnic competition perspective. According to Philip (1975:160) the "knowledge industry," or the intelligentsia, broadly defined, is grossly overrepresented in the membership of the *Plaid Cymru*. Coupland (1954) notes an overrepresentation of college graduates of all kinds. The overrepresentation of the intelligentsia in nationalist movements, in general, has been noted by Smith (1971:109-50) and Gellner (1969:168-71). The simplest explanation of their overrepre-

sentation is that they have the most to gain should the nationalist enterprise succeed—a monopoly on the roles and resources for which they now must compete. In this light, ethnic mobilization can be seen as an attempt to gain a competitive edge in the struggle for roles and resources.

It should be noted that even though the findings relative to Liberal voting support the developmental perspective, they also support the competition perspective. In some respects the competition perspective subsumes the developmental. The former argues that modernization, both political and economic, erodes small-scale, ecologically bound cultural identities; the latter argues that modernization (particularly, industrialization and urbanization) reduces the importance of "value communities."⁹ To the extent that Liberal party support in the more traditional areas of Wales is an historical residue of small-scale value communities, our findings relative to Liberal support are consistent with both perspectives.¹⁰

Finally, this study suggests that the uneven erosion of a periphery culture may present an obstacle to ethnic mobilization. The correlations presented in Table 3 and the regression analyses presented in Tables 4 and 5 underscore the cultural bases of ethnic political mobilization in Wales. If appeals to Welsh ethnicity remain strongly cultural, it is unlikely that these appeals will find much success in the industrial South of Wales. It is possible to imagine a noncultural Welsh nationalist movement finding support in these areas. Its appeal would have to be based simply

⁹ These two perspectives also converge with respect to predictions concerning the future of the Liberal party in Wales. Both would argue that in Wales the Liberal party should lose its traditional Welsh character and become more similar to the Liberal party in England. The fact that the correlation between the percentage of Nonconformist marriages and Liberal support in Wales was only .277 (see Table 3) in the election of 1974 seems to support this projection.

¹⁰ Morgan (1970:22-7), for example, argues that the endearment of the Liberal party to the Welsh occurred as a result of "The Great Election of 1868" which involved primarily local conflicts between Tory landlords and the Welsh tenantry in the countryside.

on Welsh identification, which has been shown to be more widespread and more uniformly distributed in Wales than Welsh cultural traditionalisms such as Welsh speaking (see above). This is not the present trend, however. Under the assumptions of the model illustrated in Figure 1(a), the present potential for ethnic mobilization in Wales is restricted by the waning persistence of Welsh culture.

SOCIAL LEARNING AND DEVIANT BEHAVIOR: A SPECIFIC TEST OF A GENERAL THEORY*

RONALD L. AKERS, MARVIN D. KROHN, LONN LANZA-KADUCE,
AND MARCIA RADOSEVICH

University of Iowa

American Sociological Review 1979, Vol. 44 (August):636-655

A social learning theory of deviant behavior is tested with survey data on adolescent drinking and drug behavior. The theory is strongly supported. The major explanatory variables from that theory, *differential association*, *differential reinforcement*, *definitions*, and *imitation* combine to account for 68% of the variance in marijuana use (29% of abuse) and 55% of the variance in alcohol use (32% of abuse) by adolescents. The study demonstrates that central learning concepts are amenable to questionnaire measurement, and the findings indicate that social learning theory will do well when tested with other forms of deviant behavior.

INTRODUCTION

In the last decade we have seen a dramatic shift away from sociological explanations of deviant behavior toward developing theoretical perspectives on societal reactions to and definitions of deviance and crime. Labelling and conflict formulations have become major foci of sociological theorizing as well as the sounding boards for most of the controversy and discourse in the field of deviance. This shift in focus was deemed necessary to redress the previous imbalance of attention to the deviant behavior itself (Akers, 1968), and it clearly has had that effect. Unfortunately, it also has led to the neglect of theoretical developments in the etiology of deviant behavior. Neither labelling nor conflict perspectives has offered a general explanation of de-

viant behavior, although some conflict theorists have offered preliminary but incomplete efforts in that direction (Taylor, et al., 1973; Spitzer, 1975). There have been other efforts directed toward explaining deviant behavior, but these have been fairly narrow in scope; they have usually been limited either to a specific type of deviant behavior or to a restricted range of substantive variables. For example, a good deal of attention has been paid to the modern resurrection of deterrence theory (Gibbs, 1975; 1977; Waldo and Chiricos, 1972; Tittle, 1975; Silberman, 1976; Erickson et al., 1977; Meier and Johnson, 1977; Geerken and Gove, 1977). The scope of deterrence theory has been changed little, however, since its statement by the classical criminologists two centuries ago and is limited to the actual or perceived certainty, severity, and celerity of formally administered legal sanctions for violations of the criminal law. Another example is Travis Hirschi's (1969) control (social bonding) theory which is a more general explanation of deviance than deterrence theory, but which is, in turn, primarily restricted to informal social control which comes from individuals being bonded to groups and institutions.

The most notable exception to the diminished attention to general explanations of deviant behavior is a form of social learning theory developed first by Robert

* Direct all communications to: Ronald L. Akers; Department of Sociology; University of Iowa; Iowa City, IA 52242.

The research was conducted while the authors were on the research staff of The Boys Town Center for the Study of Youth Development (Boys Town, Neb.). We gratefully acknowledge the support of the Center and express our appreciation to its director, Dr. Ronald Feldman and his computer, library, and administrative staff for their fine cooperation. We especially thank Matthew Lambert for the fine job he did for us on the project. Appreciation is expressed to the school officials, teachers, and students who cooperated in the survey. We are also appreciative of the parents who agreed to have their sons and daughters take part.

L. Burgess and Ronald L. Akers as differential association-reinforcement theory (Burgess and Akers, 1966; Akers et al., 1968) and elaborated on later by Akers (1973; 1977). As the name which Burgess and Akers originally chose to apply to this theoretical perspective makes clear, it was constructed as a revision of Edwin H. Sutherland's differential association theory (Sutherland, 1947; Sutherland and Cressey, 1974) in terms of general behavioral reinforcement theory (Skinner, 1953; 1959; Bandura and Walters, 1963; Bandura, 1969; 1977; Staats, 1975).¹ Social learning theory as a general perspective in deviance is part of a larger move toward incorporation of modern behaviorism into sociological theory (Homans, 1961; Burgess and Bushell, 1969; Kunkel, 1975; Hamblin et al., 1971; Emerson, 1969; 1972; Kunkel and Nagasawa, 1973; Burgess and Nielsen, 1974; Chadwick-Jones, 1976; for reviews of the relevance of behavioral theory for sociology see Friedrichs, 1974; Tarter, 1973). As such it is a theoretical perspective which is compatible with the more specific forays into the explanation of deviant behavior. Indeed, the major features of such theories as deterrence and control theories (Hirschi, 1969) can be subsumed under the principles of social learning theory (Akers, 1977; Conger, 1976; 1977; Feldman, 1977). However, all too often the relevance for social learning theory of some of the deviance research has been ignored or unrecognized even when the authors employ central learning concepts such as reinforcement (Harris, 1975; 1977; Eaton, 1974; Meier and Johnson, 1977; Hirschi and Hindelang, 1977). This inattention is regrettable for, while other theories delineate the structural variables (class, race, anomic conditions, breakdown in social control, etc.) that yield differential

rates of deviance, social learning stresses the behavioral mechanisms by which these variables produce the behavior comprising the rates. As such, social learning is complementary to other sociological theories and could be used to integrate extant formulations to achieve more comprehensive explanations of deviance (in this regard see Akers, 1977:63-8).

The basic learning principles on which this theory is based have received empirical support under laboratory and applied experimental conditions (see Skinner, 1953; Honig, 1966; Ullmann and Krasner, 1969; Bandura, 1969; 1977; McLaughlin, 1971; Staats, 1975). Also, prior research has been supportive of differential association theory (J. Ball, 1957; Short, 1957; Voss, 1964; R. Ball, 1968; Krohn, 1974; Jensen, 1972; Burkett and Jensen, 1975). However, there has been little direct research on learning principles as applied to deviant behavior in natural settings. Akers (1977) has organized a large body of existing research and theory on a wide range of deviant behavior supportive of or consistent with social learning, but his effort is a post hoc application of theoretical principles for he does not present research designed explicitly to test propositions from the theory (in this regard see also Feldman, 1977). The results of other studies are consistent with Akers's social learning approach (Jessor and Jessor, 1975; Thomas et al., 1975), and a couple of studies explicitly testing social learning using secondary data analysis have found support for it (Anderson, 1973; Conger, 1976). However, more crucial and conclusive tests await collecting the relevant primary data in the community. The present study does that. Our purpose here is to report a specific test of social learning theory using standard sociological techniques of data collection and data analysis.

¹ The label *social learning* has been applied to other theories based on reinforcement principles but the Burgess and Akers formulation is the first and only one which ties general learning theory to a long-standing sociological theory and is directed towards specific forms of deviant behavior (crime, delinquency, drug addiction, suicide, etc.). It is to this theory that social learning usually refers when used here. It will be clear from the context when this is not the case.

STATEMENT OF SOCIAL LEARNING THEORY

The social learning theory tested here is summarized from Akers (1977:39-68). The primary learning mechanism in social behavior is operant (instrumental) conditioning in which behavior is shaped

by the stimuli which follow, or are consequences of the behavior. Social behavior is acquired both through direct conditioning and through *imitation* or modelling of others' behavior. Behavior is strengthened through reward (positive reinforcement) and avoidance of punishment (negative reinforcement) or weakened by aversive stimuli (positive punishment) and loss of reward (negative punishment). Whether deviant or conforming behavior is acquired and persists depends on past and present rewards or punishments for the behavior and the rewards and punishments attached to alternative behavior—*differential reinforcement*. In addition, people learn in interaction with significant groups in their lives evaluative *definitions* (norms, attitudes, orientations) of the behavior as good or bad. These definitions are themselves verbal and cognitive behavior which can be directly reinforced and also act as cue (discriminative) stimuli for other behavior. The more individuals define the behavior as good (positive definition) or at least justified (neutralizing definition) rather than as undesirable (negative definition), the more likely they are to engage in it.

The reinforcers can be nonsocial (as in the direct physiological effects of drugs) as well as social, but the theory posits that the principal behavioral effects come from interaction in or under the influence of those *groups which control individuals' major sources of reinforcement and punishment and expose them to behavioral models and normative definitions*. The most important of these groups with which one is in *differential association* are the *peer-friendship* groups and the *family* but they also include schools, churches, and other groups. Behavior (whether deviant or conforming) results from greater reinforcement, on balance, over punishing contingencies for the same behavior and the reinforcing-punishing contingencies on alternative behavior. The definitions are conducive to deviant behavior when, on balance, the positive and neutralizing definitions of the behavior offset negative definitions of it. Therefore, deviant behavior can be expected to the extent that it has been differ-

entially reinforced over alternative behavior (conforming or other deviant behavior) and is defined as desirable or justified. Progression into more frequent or sustained use and into abuse is also determined by the extent to which a given pattern is sustained by the combination of the reinforcing effects of the substance with social reinforcement, exposure to models, definitions through association with using peers, and by the degree to which it is not deterred through bad effects of the substance and/or the negative sanctions from peers, parents, and the law.

The social learning theory proposes a process which orders and specifies the interrelationships among these variables. Differential association, which refers to interaction and identity with different groups, occurs first. These groups provide the social environments in which exposure to definitions, imitation of models, and social reinforcement for use of or abstinence from any particular substance take place. The definitions are learned through imitation, and social reinforcement of them by members of the groups with whom one is associated, and once learned, these definitions serve as discriminative stimuli for use or abstinence. The definitions in interaction with imitation of using or abstinent models and the anticipated balance of reinforcement produces the initial use or continued abstinence. After the initial use, imitation becomes less important while the effects of definitions should continue (themselves affected by the experience of use). It is at this point in the process that the actual consequences (social and nonsocial reinforcers and punishers) of the specific behavior come into play to determine the probability that use will be continued and at what level. These consequences include the actual effects of the substance at first and subsequent use (the perception of which may, of course, be modified by what effects the person has previously learned to expect) and the actual reactions of others present at the time or who find out about it later, as well as the anticipated reactions of others not present or knowing about the use.

From this depiction of them as aspects

of the same learning process, we expect the independent variables to be positively interrelated, and we examine the zero-order relationships among them. Nonetheless, the major variables are conceptually distinct and our measures are empirically distinct enough that we do not expect their interrelationships to preclude separate independent effects. Thus, we also empirically order the independent variables in terms of how much variance is explained in the dependent variables. We test the general hypothesis from the theory that adolescent marijuana and alcohol use and abuse are related to each of the major sets of variables and to all of them combined.

Specifically, we expect that for both alcohol and drugs, the probability of abstinence decreases and the frequency of use increases when there is greater exposure to using rather than to abstinent models, when there is more association with using than with abstinent peers and adults, when use is differentially reinforced (more rewards, fewer punishers) over abstinence, and when there are more positive or neutralizing than negative definitions of use. Similarly, among users the probability of abuse increases with more exposure to abusing rather than moderate or abstinent models, more association with high frequency users or abusers, greater differential reinforcement for abuse over more moderate use, and with more positive and neutralizing rather than negative definitions of use.

RESEARCH ON ADOLESCENT DRUG AND ALCOHOL BEHAVIOR

Adolescent drug and drinking behavior is a particularly strategic area for the current effort for two reasons. First, the area is characterized by the narrow scope of current theories of deviant behavior outlined above. The research has been largely restricted to the prevalence and sociodemographic and social-psychological correlates of teenage drinking and drug use (Abelson et al., 1973; Johnston, 1973; Block et al., 1974; National Commission on Marijuana and Drug Abuse, 1972; Drug Abuse Council, 1975; Rachal et al., 1975; O'Donnell et al.,

1976). Little has been done to develop and test explanations of the behavior drawn from general theories. (For a full and comprehensive review of the theory and research literature on adolescent drinking and drug use, see Radosevich et al., forthcoming.) One notable exception to this is the work of the Jessors (Jessor et al., 1968; 1970; 1973; Jessor and Jessor, 1975; 1977; Jessor, 1976) who have built a social-psychological theory of "problem behavior" (deviance) which incorporates part of Rotter's (1954) learning theory (locus of control) and other personality and social variables. Their theory, which is also a version of social learning, consists of three categories of variables—personality, social, and behavioral. Their findings tend to support parts (primarily the social component) of the theory. The Jessors' findings point to the second reason why adolescent drug use and drinking promises to be a fruitful area in which to examine social learning theory; that is, the research on social psychological correlates of drug use and drinking lends support to the relevance of many of the variables in the social learning theory tested here. For instance, research consistently finds that those holding tolerant or positive attitudes toward a substance are much more likely to use it than those holding negative attitudes toward it (Fejer and Smart, 1973; Johnston, 1973; Jessor et al., 1973; Calhoun, 1974; Kendall, 1976). Also, peer and parental influence have been found to be important variables in teenage drug and drinking behavior. Users are more likely than abstainers to associate with peers who are also users and this relationship remains whether friends' use is measured by or independently of the individual's perception of friends' use. (For a review of this research on parental and peer influences see Akers, 1977; recent studies to see are Pearce and Garrett, 1970; Kandel, 1973; 1974; Jessor et al., 1972; O'Donnell et al., 1976; Tec, 1974a; 1974b; Krohr, 1974; Wechsler and Thum, 1973; Kendall, 1976; Lawrence and Velleman, 1974.) Further, the research findings seem to be consistent with the causal ordering of these variables proposed by social learning: the youngster associates with peers who are users, learns defini-

tions favorable to use of the substance, and then uses (Jessor et al., 1973; Krohn, 1974).

METHODOLOGY

Sample and Procedure

Data were collected by administering a self-report questionnaire to 3,065 male and female adolescents attending grades 7 through 12 in seven communities in three midwestern states. A two-stage sample design was followed. First, we selected schools from within each participating school district which were representative in terms of school size and location within the district. In smaller districts this meant selecting all or most of the junior and senior high schools in the district. Secondly, we sampled two to three classrooms (depending on school and average class size) per grade level from among the required or general enrollment classes. Thus, although classrooms were sampled, each student has an approximately equal chance of being included in the sample.² The questionnaire (which

was pretested in a district not included in the final sample) was administered to all students in attendance in the selected classes on the day of the survey who had obtained written parental permission. The attrition from this parental permission procedure combined with absenteeism on the day of the survey was not great and 67% of the total number of students enrolled (95% of those with parental permission) in the sampled classes completed the questionnaire.³

A small subsample, purposively sampled from among respondents who volunteered in five of the seven districts ($n=106$, approximately 5% of the sample in these districts), was interviewed two to eight weeks after the administration of the questionnaire. The follow-up interview was intended to serve as a reliability and partial validity check on the questionnaire responses and to provide additional descriptive information. The interviews were conducted individually in private rooms at school during school hours.

Reliability and Validity

Prior research has consistently shown that the self-report questionnaire technique is reliable and valid in measuring adolescent delinquent, drug, and drinking behavior (Hardt and Peterson-Hardt, 1977; Groves, 1974; Block et al., 1974; Single et al., 1975; Whitehead and Smart, 1972). Our own checks in the present research confirm this. Internal consistency on interlocking questions was high

² Our primary aim was to test an explanation of drug and drinking behavior and we had no plans to generalize about the prevalence or sociodemographic variations to a wider national or regional population. Therefore, there was no attempt to get a probability sample or to insure that the total sample was regionally or nationally representative. We did plan to report findings to the participating school districts and to generalize findings within each district. Also, we wanted to follow a design which would require the involvement of as few schools and school personnel as possible, which would minimize adjustments needed in the school routine, and which would facilitate administration of the questionnaire to groups of respondents. The sampling of a limited number of classrooms from within each selected school best served these purposes. We believe that being alert to the problem of minimizing interference of the survey into the school routine and proposing the sampling procedure which we followed was a significant element in gaining the approval and cooperation of the school officials. The resultant sample was sufficiently representative within each district that we could make reasonable generalizations about the drug and drinking problem in the district. Whether two or three classes per grade level were sampled from each school depended on the size of the classes. We tried to include enough classes to secure responses from at least 10% of the total school enrollment or a minimum of 100 respondents per school, whichever was greater, to help protect the confidentiality of respondents in the smaller schools.

³ Overall, 74% of the parental permission forms distributed were returned (the lowest percentage of return in a district was 62% and the highest return rate was 93%). The forms were first distributed by the researchers in the classrooms one week before the survey; then, one more visit was made to the classrooms to remind students to return the forms. For some classes, telephone calls were made to the parents of those students who had not returned the form. Without this call-back procedure, buttressed by telephone calls, the return rate would have been smaller. For the sample as a whole, 95% of those returning forms were granted parental permission to take part in the survey (we asked that the forms be returned whether permission was granted or denied). Ninety-five percent of those attended class and completed the questionnaire on the day of the survey.

(Gammas=.91 and higher). In addition, a comparison of the responses to the frequency and quantity of use questions on the questionnaire with responses to the same items given at the time of the interview demonstrated a high degree of reliability (Gammas=.89 and higher). Without exception the interview respondents reported that they believed the researchers' assurances of confidentiality and that no one but the researchers would have access to identifiable answers; thus, all said that they felt secure in responding and answered questions both on the questionnaire and in the interview honestly.⁴

⁴ Careful steps were taken to protect the rights of both questionnaire and interview respondents and of the school districts. The usual university procedures were followed regarding approval of the project's procedures for protection of the rights of research participants. At the time of the first visit to the classrooms, the students were informed of the survey and each one present was given an envelope containing a letter explaining the purpose and content of the study to the parents and the parental consent form mentioned in fn. 3. The students were told that participation in the study was completely voluntary. It was made clear that no student had to participate as a condition for class credit or any other school requirement and that approval of the study by the district and school officials in no way made participation mandatory. All of the responses were and are held in strictest confidence. In five of the districts, respondents who were willing to be interviewed later were asked to indicate that willingness and to sign their questionnaires. Also, it was possible for anyone to place his or her name on the questionnaire even if not volunteering for an interview (and many did just that). To protect the confidentiality of those volunteering for an interview, all respondents, whether signing the name sheet or not, separated it from the rest of the questionnaire and deposited it in a separate box from the one in which the completed questionnaires were deposited. Only the research staff had and has access to the name lists which, when not in a locked drawer, were kept in a bank safety deposit box. All other respondents in these districts and all respondents in the other two districts where no interviews were conducted were anonymous. At the interview each respondent was again informed of the confidentiality of the information given. Upon completion of the interview, each respondent was paid the previously stipulated amount of \$2.50 and signed a sheet acknowledging the voluntary nature of the interview and receipt of the payment. The list of interviewee's names was treated in the same way as the name sheets mentioned above. We also protected the identification of the school districts participating in the study. No community, school district, or school has been or will be identified by name in reports or disseminated findings.

Measurement of Variables

Dependent variables. Abstinence-use of alcohol and marijuana is measured by a six-point frequency-of-use scale ranging from nearly every day to never. A quantity frequency (Q-F) scale was also computed but since there is a near perfect correlation between the Q-F scale and the frequency-of-use scale, the analysis here includes only the latter measure.⁵

Abuse among users is measured by combining responses to the frequency questions with responses to a question asking the respondents to check whether or not they had experienced on more than one occasion any of a list of problems while or soon after using alcohol or marijuana.⁶ This combination produced a four-point abuse scale ranging from heavy abuse to no abuse.

Independent variables. From the summary of social learning theory presented above it can be seen that the main concepts to be measured are *imitation*, *differential association*, *definitions*, and *differential reinforcement*. For the present analysis, we distinguish between differential reinforcement comprised of social reinforcement combined with non-social reinforcement (experienced or anticipated drug or alcohol effects) and that comprised only of social reinforcement. Each of the resulting five concepts are operationalized by a set of items measuring different aspects of each concept. (The Appendix provides a brief description of the way the five concepts are measured.)

⁵ Alcohol use was measured by responses to separate questions on beer, wine, and liquor. The highest percentage of use and most frequent use was reported for beer, and since there is a very high correlation between use of the three forms of alcohol, use of alcohol in this analysis is measured only by reported frequency of use of beer.

⁶ The problems included "had an accident," "couldn't remember later what I had done," "used more than I had planned." This is a fairly standard use of "problems associated with" as a nonclinical measure of abuse of some substance. It should not be confused with our measures of positive and negative consequences of use for the differential reinforcement variables. The questions used to measure abuse were asked separately from and never combined with the questions used to measure differential reinforcement.

These five clusters of variables (a total of 15 variables in the abstinence-use analysis and 16 variables in the abuse analysis) constitute the independent variables in this analysis.⁷

Method of analysis. Although most of the measures yield ordinal-level data, we will use multiple regression techniques. It has been demonstrated that regression can be confidently employed with ordinal data without introducing bias in the results (Labovitz, 1970; 1971; Kim, 1975). The use of regression techniques provides an overall summary of the explanatory power of the model while also allowing us to examine the unique effects of the five subsets of variables and of each separate variable.

PRESENTATION OF FINDINGS

Explaining Abstinence-Frequency of Use

The zero-order correlation matrices for the alcohol and marijuana use variables are presented in Tables 1 and 2.⁸ As expected, most of the independent variables

are related in a positive direction with variability in the strength of the relationships. Of particular interest are the relatively weak relationships of the deterrence items to the other variables, especially within the matrix on alcohol behavior. Also, note the strength of the relationships of both alcohol and marijuana use to those variables of associations with and attitudes of peers, to reinforcement balance, and to reward-costs of use, and note the interrelationships among these variables. These zero-order relationships anticipate our findings in the multivariate analysis to which we now turn.

The results of the regression analyses show strong support for the social learning theory of adolescent alcohol and drug behavior.⁹ When all the independent variables are incorporated into the full regression equation, the model explains 55% of the variance in drinking behavior (abstinence-frequency of use; Table 3) and 68% of the variance in marijuana behavior (abstinence-frequency of use; Table 4).¹⁰

The power of the full model including the five subsets of variables, therefore, is demonstrated. But, we are also interested in determining the relative predictive values of the subsets and single variables to see if each part of the theory is supported. We do this in two ways. First, we regress the dependent variables on all variables and each subset of variables in separate regression equations. This provides a partial regression coefficient for each variable in each equation and estimates of the total amount of variance explained by each subset (Tables 3 and 4). Second, we compute the proportion of variance which the remaining subsets ex-

⁷ The concepts are clearly not equal in the scope of concrete empirical phenomena to which each refers. Differential association with family, peer, and other groups exposes the adolescent to using and nonusing models and normative definitions of use. It is in interaction in these groups in which the reactions of others differentially reinforce substance use or abstinent behavior. It is in this sense, then, that the differential association could include empirical referents of each of the other concepts and a general measure of differential association (in addition to being a measure of with whom one interacts), could serve as a general, albeit indirect, index of the combined effects of social reinforcement, imitation, and exposure to normative definitions. But such an index could not distinguish among the specific mechanisms of taking on definitions, imitating, and reinforcing of behavior which occur within the groups with which one is differentially associated. The combined social/nonsocial reinforcement subset obviously includes a wider array of concrete reinforcers than the subset of only social reinforcers. But, while reinforcement is the most abstract concept, the concrete set of events to which our measures here refer makes neither the social/nonsocial reinforcement, nor the social reinforcement subset broader than the definitions subset. Since it refers specifically to observing the behavior of someone else without reference to attitudes toward or consequences of the behavior, the imitation subset represents the most limited range of phenomena.

⁸ The zero-order matrices for the abuse variables not presented here are similar to those for use.

⁹ The total N in the tables varies because of attrition due to listwise deletion of missing values. The respondents who were eliminated were not significantly different from those included on sociodemographic characteristics and on the dependent variable. We also computed the regression analysis employing pairwise deletion and obtained similar results.

¹⁰ This general level of explained variance and the relationships of the separate independent variables to the dependent variables held when we controlled for such variables as SES and sex (which were not related to the dependent variables) and when we controlled for such variables as grade in school and type of school district (which were related to the dependent variables).

* In this and in all subsequent tables independent variables have been coded such that positive coefficients indicate the theoretically expected direction.

plain when each subset in turn is eliminated from the equation. By subtracting each of these values from the proportion of variance explained by the full equation, we have a measure of how much explained variance is lost when a given subset of variables is eliminated. The larger the proportion of explained variance lost (or the smaller the explained variance remaining) when a subset is eliminated, the greater its relative explanatory power (Table 5). By analyzing the data in this fashion, we also circumvent potential problems of multicollinearity among the variables within each subset since our primary concern is with the relative explanatory power of the different subsets of variables and not with the relative power of individual variables within subsets.

With the exception of imitation, each

subset explains a substantial proportion of variance in both alcohol and marijuana use. The findings presented in Table 5 show that even when the most predictive subset of variables is eliminated the remaining variables are still able to explain 43% and 56% of the variance in alcohol and marijuana behavior, respectively. The fact that four of the five subsets of variables taken from social learning theory *each* explains a substantial proportion of the variance (and that the fifth is significantly related to the dependent variables in the expected direction) demonstrates that the theory as a whole is supported; its power is not dependent on any single component.

However, the analyses also plainly show that some subsets of variables specified by the theory are more impor-

tant than others. They are ranked in terms of relative effectiveness in explaining variance in alcohol and marijuana use as follows: (1) differential association, (2) definitions, (3) combined social/nonsocial differential reinforcement, (4) differential social reinforcement, and (5) imitation.¹¹ Not only does the differential association subset explain the highest proportion of variance, but the differential peer associa-

tion variable is the most important single variable. The definitions subset accounts for the second highest proportion of variance, and one's positive/negative definitions of the substances is the second most predictive single variable, while one's law-abiding/violating definitions rank third among the single variables. The differential reinforcements variables are next, followed by imitation variables which explain the least amount of variance in the dependent variables.

The fact of peer group influence on substance use comes as no surprise; it is documented by several previous studies. But, previous studies have not shown what the mechanisms are by which peer influence is exerted, and why, therefore, peer group association is so important. Our data show, as predicted by social learning theory, what these mechanisms are—friends provide social reinforcement

¹¹ It is possible that the relative explanatory power of each subset may be due in part to the different number of variables that are contained within each subset. To examine this possibility we selected the most predictive variable from each subset and entered those variables in a multiple regression equation. The result produced no change in the rank ordering of the concepts in either the alcohol or marijuana equation. This also allowed us to examine the possible effects of multicollinearity within subsets on the relative explanatory power of single variables. Again the results were similar to those obtained above, indicating small multicollinearity effects.

or punishment for abstinence or use, provide normative definitions of use and abstinence, and, to a lesser extent, serve as admired models to imitate. This is indicated by the fact that these other variables, on their own, explain a substantial amount of the variance in marijuana and alcohol behavior when the effect of the differential peer association variable is removed. The fact that differential interaction explains more variance in the dependent variables than do the reinforcement, definitions, and imitation variables indicates that there may be additional variables at work in interaction beyond those identified by social learning theory, that there are additional effects of the mechanisms specified by our theory which are not captured by our measures of them, or that there are effects of other learning variables which we have not included (e.g., discriminative stimuli in the interaction setting in which reinforcement takes place).

Since social learning theory includes modelling as an important part of the process, the lower levels of variance explained by our imitation measures may seem surprising. However, the relatively weak effect of the imitation subset on our frequency of use and abuse measures was not unexpected. First, imitation refers to the narrowest empirical phenomenon among our measures (see footnote 7) and while, as we have noted, multicollinearity is not a severe problem, the interrelationships specified in the theory would indicate that removing imitation has less effect because its impact is still reflected to some extent in the remaining broader measures. Second, and more important,

as indicated in the process outlined in the statement of the theory above, imitation in social learning theory is considered to have its greatest effect in the first acquisition or initial stages of behavior while the associational, reinforcement, and definitional variables are more important in the maintenance of a behavioral pattern. We expect imitation to be more important in first starting to use than we find it to be in explaining frequency of use as analyzed here (but still probably not more important than definitional and reinforcement variables). The analysis here which employs frequency of using as the dependent variable militates against finding a large effect for imitation variables. We would expect imitation to be even less important in accounting for maintenance of abusive patterns of use.

It is evident that social learning theory has been shown to be a powerful explanation of whether youngsters abstain from or are users of alcohol and marijuana. As predicted by the theory, the adolescents in our sample use drugs or alcohol to the extent that the behavior has been differentially reinforced through association in primary groups and defined as more desirable than, or at least as justified as, refraining from use. The next step in testing the validity of this perspective will be to examine how well these same variables account for levels of abuse of alcohol and drugs.

Explaining Abusive Patterns of Use

The results of the analyses of alcohol and marijuana abuse among adolescents are presented in Tables 6, 7, and 8. For these analyses, only users are included.

Full Equation R ² =	.315		.389	

The results parallel those of the analyses of abstinence-frequency of use reported above. Both marijuana and alcohol abuse are strongly related to the social learning variables. The proportion of variance explained in use-abuse is well below the explained variance in abstinence-frequency of use but it is still substantial—32% and 39% of the variance in alcohol and marijuana abuse, respectively. The differential association subset again explains the greatest proportion of variance (Tables 6 and 7), but, even without the differential association variables, the other variables in the model do well in accounting for the variance (22% and 30%; Table 8).

The variables are not ordered in terms of relative effectiveness in predicting abuse in the same way they were ranked in explaining abstinence-use. In the analysis of abstinence-use, definitions were the second most effective subset, whereas this subset ranks fourth in accounting for use-abuse while the differential reinforcement variables are ranked higher. In substance abuse the user comes more and more to respond to direct reinforcement, especially from the drug effects themselves; definitions would be expected to play a less significant role. This is shown fairly clearly when we examine the effect of adding an alcohol and marijuana effects variable which was not included in the previous analysis of abstinence-frequency of use. This variable was measured by asking using respondents to report the effects which they usually obtained from smoking marijuana or

drinking alcohol.¹² This variable has the largest beta weight among the single variables making up the social/nonsocial differential reinforcement subset and ranks second for marijuana abuse and third for alcohol abuse among the entire set of single variables.

The variable of parental reaction appears to be related to abuse in the direction opposite to that found in the analysis of use. For the latter a lower probability of use is found for those reporting the strongest or harshest parental punishment while for the former a lower probability of abuse is found for those reporting lesser punishment or no parental response. A cross-tabular examination of these relationships reveals a curvilinear relationship between parental reaction and both adolescents' use and abuse of alcohol and marijuana. That is, higher frequency of use and abuse is found with parental response (actual or anticipated) at both the most lenient (encourage or do nothing) and the harshest end of the scale (take some drastic action such as kick the youngsters out of the house or turn them over to the police). The highest probability of abstinence and the lowest levels of use and abuse are found among adolescents who report that their parents have responded or would respond to their use with a moderate negative reaction such as

¹² Since abstainers could only report anticipated effects, the question of actual physical effects usually obtained from using the substances could not be included in the analyses of abstinence-frequency of use. Only among users are we able to differentiate between social and nonsocial reinforcement.

a scolding. Our post hoc interpretation of these relationships is that anticipated parental punishment is a deterrent to use and sustains abstinence. Even after use has begun a reasonable amount of parental punishment holds down the chances of increasing frequency of use or moving into abuse. However, once adolescents have gotten into heavy use or abuse, parental reaction has lost its effect and the increasing abuse of the substances by their children may produce ever harsher reactions by parents in increasingly desperate attempts to do something about it.

While not contradictory to the theory, neither the difference between the amount of variance explained in abstinence-frequency of use and that explained in use-abuse for both alcohol and marijuana behavior nor the difference between the amount of variance explained in alcohol behavior and the amount explained in marijuana behavior was specifically anticipated. The lower level of explained variance in substance abuse than in substance use may be due simply to the fact that the variance in the abuse variables is restricted, thereby producing attenuation in the total variance explained. The differences in the explained variances in alcohol and marijuana behavior may be an artifact of our measurements, may indicate that the stimuli surrounding alcohol behavior are more uniform than those surrounding marijuana behavior, or may point to some real difference in the ability of the theory to account for the two kinds of substance use.

SUMMARY AND CONCLUSIONS

In the past decade sociological attention in the study of deviance has shifted to explanations of the control system and away from the equally important task of proposing and testing general explanations of deviant behavior. We have presented a social learning perspective on deviant behavior developed during this same time period which holds promise as a general theory of the process of coming to engage in deviant acts but which had not been tested with primary data collected in the community and subjected to multivariate

analysis. We have tested it here on specific forms of adolescent deviance—drug and alcohol use and abuse.

The results of the tests support the theory. All of the dependent variables are strongly related to the social learning variables of differential association, definitions, differential reinforcement, and imitation. The most powerful of these independent variables is differential association. The other variables stand on their own, however, and explain substantial portions of variance even without the differential association measures (except for imitation which is the weakest of the variables for use and explains almost none of the variance in abuse).

The strength of empirical support for the theory suggests that the theory will have utility in explaining the use and abuse of other substances by adolescents. These findings also indicate that social learning theory will do well when tested with other forms of deviant behavior in future research. Future research could test the general theory in any number of specific contexts. We believe that our study demonstrates that the central learning concepts are amenable to meaningful questionnaire measurement and that social learning theory can be adequately tested with survey data. This is important given the lack of survey data measuring social learning concepts, and the collection and analysis of cross-sectional data presented here is a necessary step, but a first step, nonetheless. Therefore, the next steps in testing social learning theory not only should include analysis of the use and abuse of stronger and more severely disapproved substances than marijuana and alcohol (stimulants, depressants, psychedelics, and opiates), but also should include the collection of longitudinal data (Jessor and Jessor, 1977; Kandel, 1978). Longitudinal data will allow more adequate testing of the process of learning and temporal-ordering of variables in the theory.

APPENDIX

LIST OF SOCIAL LEARNING VARIABLES*

I. Imitation

1. *Index of Imitation*

Total of all the "admired" models (parents, friends, other adults, etc.) whom the respondent reports having observed using the substance.

II. Definitions Favorable or Unfavorable to Use

2. *Techniques of Neutralization Scale*

A scale of three items measuring Sykes and Matza's (1957) "techniques of neutralization" or definitions justifying or excusing use by "denial of injury," "denial of responsibility," or "condemning the condemners." Item to scale interrelation for the scale referring to alcohol range from .68 to .76; for marijuana the range is from .68 to .78.

3. *Scale of Law-Abiding or Law-Violating Definitions*

A scale of items measuring obedient or violating attitudes toward the law in general and alcohol and drug laws in particular. Item to scale intercorrelations range from .53 to .76.

4. *Positive or Negative Definitions of Use*

Respondents' own approval or disapproval of use.

III. Differential Association

5. *Significant Adults' Norm Qualities*

Respondents' perception of the approving-disapproving attitudes toward use held by adults whose opinions they value.

6. *Significant Peers' Norm Qualities*

Respondents' perception of the approving-disapproving attitudes toward use held by other teenagers whose opinions they value.

*The variable numbers in this list correspond to the variable numbers in the regression tables. For all items, questions were asked separately for alcohol and marijuana. Copies of the questionnaire and list of concepts measured by questionnaire items are available on request.

7. *Differential Peer Association Scale*
A scale of three items measuring how many of respondents' best friends, friends with whom they associate most often, and friends whom they have known for the longest time use the substance. Item to scale intercorrelations of the alcohol scale range from .85 to .96; for marijuana the range is from .83 to .96.
- IV. *Differential Reinforcement: Social*
 8. *Praise for Not Using*
Respondents' report as to whether or not friends, parents or both encouraged them *not* to use.
 9. *Friends' Rewarding or Punishing Reactions*
Respondents' report of anticipated or actual positive or negative sanctions of friends to respondents' use of the substance, ranging from encouraging their use to turning them in to the authorities.
 10. *Parents' Rewarding or Punishing Reactions*
Respondents' report of anticipated or actual positive or negative sanctions of parents for respondents' use of the substance, ranging from encouraging their use to turning them in to the authorities.
 11. *Informal Parental Deterrence*
Respondents' perceived probability that their parents would catch them if they used the substance.
 12. *Formal Deterrence*
Respondents' perceived probability that the police would catch them if they used the substance.
13. *Interference with Other Important Activities*
Respondents' perception of the extent to which using the substance would interfere with their participation in activities (i.e., school work, athletics, etc.) important to them.
- V. *Differential Reinforcement: Combined Social/Nonsocial*
 14. *Index of Social/Nonsocial Rewards Minus Costs of Use*
The total good things from a list of positive drug effects and social outcomes which the using respondent checked as having actually experienced and the nonusing respondents checked as what they perceived they would experience as a result of using the substance *minus* the total bad things checked (there is an equal number of good and bad possible consequences in the list).
 15. *Overall Reinforcement Balance*
Respondents' assessment of whether on balance mostly good things (such as "a good high or get along better with others") or mostly bad things (such as "a bad high or get into trouble") would (as perceived by nonusers if they were to use) or did (as reported by users when they used the substance) happen.
 16. *Usual Effects Felt When Used*
Respondents' report of the effects the substance usually has on them (from no effect, to mostly good, to mostly bad effects). Asked only of those using more than once.

RESEARCH NOTE

AMERICAN JEWISH DENOMINATIONS: A SOCIAL AND RELIGIOUS PROFILE*

BERNARD LAZERWITZ AND MICHAEL HARRISON

Bar-Ilan University

American Sociological Review 1979, Vol. 44 (August):656-666

This paper furthers our understanding of American religious pluralism by analyzing Jewish denominational patterns as revealed by data from the National Jewish Population Survey. A clear ranking among the denominational subgroups emerges, ranging from those identifying with Orthodoxy, to those identifying with Conservative Judaism, Reform, and finally those having no denominational preferences. This last group has the lowest levels of religious and ethnic identification. The subgroups closer to the Orthodox pole have higher levels of Jewish identification and observance, and are somewhat lower in socioeconomic status and voluntary association activities. The socioeconomic differences are considerably smaller than they are known to have been historically, but differences in the degree of Americanization, as indicated by the number of generations in the United States, remain strong. The data also show that marital patterns and certain secular attitudes and behavior are associated with denominational identification and synagogue membership. Analogies are suggested between the ideological and behavioral divisions within American Judaism and those found in Protestantism. Our findings point to the durability of a denominationalism which is becoming increasingly independent of its classic social and economic sources.

Religious associations have historically been one of the most prominent forms of voluntary association in American society. In addition to differing along theological lines, religious groups have often mirrored important social divisions within the American population and, thereby, have formed focal points for the expression of the interests and sentiments of socially distinct subgroups. Within American Protestantism this tendency toward differentiation achieved legitimation in the denominational principle (Mead, 1963; Parsons, 1960:295). The

character and functioning of American Protestant denominations has been the subject of a considerable body of research and commentary (e.g., Niebuhr, 1929; Anderson, 1970; Berger, 1969; Gaustad, 1962; Glock and Stark, 1965; Greeley, 1972; Laumann, 1969; Stark and Glock, 1968; Wilson, 1968a, 1968b).

On the other hand, less attention has been directed to the development of analogous denominational tendencies within smaller non-Protestant groups. Of particular interest is the development of a tripartite denominational structure within American Judaism. Several historical analyses trace the development of the American Jewish denominations (e.g., Sklare, 1972; Steinberg, 1965; Blau, 1969; 1976; Glazer, 1972; Liebman, 1965; 1973; Poll, 1969). In addition, surveys of individual metropolitan Jewish communities, such as those by Axelrod (1967), Dashefsky and Shapiro (1974), Goldstein and Goldscheider (1968), Lazerwitz (1973a), and Sklare and Greenblum (1967), provided some data on the characteristics of the members of these denominations. These local studies, however, typically suffer from sample designs that omit mar-

The authors thank the Council of Jewish Federations and Welfare Funds for permission to use and publish these data from the survey it commissioned. They also thank the Institute for Jewish Policy Planning and Research for financial support. The computer installations of the University of Missouri and Bar-Ilan University were very generous in allotting free computer time for analysis. Credit for their fine research assistance must also be given to Mr. Patrick Corkery, Mr. William McKenzie, Mr. Randy Meyer, Miss Sarah Cohen, Miss Dahlia Rachman, and Mr. Moti Miron. We also acknowledge the helpful comments of Professors Alan Silver, J. Alan Winter, C. Liebman, and S. Weitman.

ginal members of the Jewish population, have limited sample sizes, and do not lend themselves to generalizations about American Jewry as a whole. Moreover, these local studies typically pay too little attention to individuals without any denominational preference or to those with denominational identifications who do not join synagogues. Large-scale sample surveys of the general American population cannot illuminate differences within American Jewry, since they include too few Jewish respondents.

In this report we analyse nation-wide survey data on the American Jewish population which finally provide an authoritative basis for the development of generalizations about the ethnic, religious, and social characteristics of Jewish Americans who do and do not, identify and affiliate with the major denominations. This first report presents these data in a form which permits comparisons with the available data on Protestant Americans. Subsequent reports from this study will examine the data's implications for some of the important theoretical questions about the sources and consequences of denominational differentiation. Even in the basic form in which they are presented here, these data make it clear that Jewish denominational involvement and differentiation are empirically more durable and important than they have previously been considered to be.

METHODS

Sample Design

The National Jewish Population Survey (NJPS) was a national survey of the United States Jewish population conducted from the early spring of 1970 to the end of 1971 for the Council of Jewish Federations and Welfare Funds. The sample yielded 5,790 household interviews at a 79% response rate. For the purpose of this survey, Jews were defined as persons who reported themselves Jewish or, failing this, as a person who had at least one Jewish parent. The sample design had to take into account that American Jewry constitutes only a few percent of the total American population, that a sizable pro-

portion do not live in neighborhoods with high concentrations of Jewish residents, and that many are not listed on readily available communal lists. The final design was a complex, multistage two-phase, disproportionately stratified, cluster sample. This design was guided by a variation of the city directory/block supplement sampling approach described in Lazerwitz (1968:314-20) and Kish (1965:352-8). Details on the sample, its response characteristics, and generalized sampling errors appear in Lazerwitz (1973b; 1974; 1978a). When a sampled household was found to contain a Jewish resident, basic information about the family was obtained and, via the Kish (1949) technique, one adult Jewish respondent was then selected from among all the Jewish adults in residence. (At this survey phase, there was additional subsampling within just the New York area.) Interviews with 4,305 adult Jewish respondents from this final sampling stage provide the national data reported here.

Variable Definition and Measurement

For reference, we summarize here the variables analyzed in this report:

(1) *Jewish denominational identification and synagogue membership.* Respondents were classified into four categories on the basis of their expressed denominational identifications. Individuals who did not identify with a denomination or said they were "just Jewish," were classified as having no denominational identification. In addition, respondents were asked whether they were members of a synagogue.

(2) *Jewish identification indices.* A set of items indicative of various aspects of religious and ethnic identification were used to create indices of the nine dimensions of Jewish identification described in Lazerwitz (1973a:205-10).¹ In brief these indices are:

¹ Details on these indices are available from the authors. There have been some limited operational changes in the indices of these dimensions in response to changes in specific questions on the national survey in contrast to the earlier Chicago area survey used in Lazerwitz (1973a).

Childhood home Jewish background—the Jewish aspects of respondents' childhood homes, covering items such as parental religious involvement, their Jewish organizational activities, and home holiday celebrations.

Jewish education—the type and amount received during childhood and adolescence.

Religious observance—respondents' present synagogue attendance, home religious observances of the Shabbat and the annual cycle of religious holidays, and observance of the dietary laws.

Pietism—observance of the more individualistic forms of religious expression such as private prayers and fasting.

Jewish ideology—extent to which being Jewish and retaining Jewish values are felt to be desirable and intrinsically worthwhile.

Ethnic community involvement—the extent to which a respondent's dating, courtship behavior, friends, family life, and social life have been confined to Jews.

Jewish organizational involvement—extent of membership, activity, and leadership in Jewish voluntary associations.

Jewish socialization of one's children—degree of respondent's past, present, and anticipated efforts to socialize his or her children into Jewish life.

Concern for world Jewry—attitudes toward Israel and degree of concern over the fate of Jews in difficult circumstances in the rest of the world.

(3) *Secular correlates of Jewish identification*. The NJPS data permitted the measurement of the following types of behavior and attitudes:

Membership and participation in general community voluntary associations—here summarized by an index which is a slightly modified version of the Chapin scale.

Political orientations—an index of attitudes to such issues as school busing and aid to welfare recipients. More liberal responses received higher index scores.

Religious background of spouse—information on the religious and denominational preference of the wives of male respondents when the couple first met.

(4) *Socioeconomic characteristics*. This variable covered respondent's education, the occupation of the head of the household, and total family income for the year prior to the survey.

(5) *Demographic characteristics*. This variable covered respondent's sex and age.

Generation in the United States—ranked as respondent foreign born; both parents foreign born; both parents born in the United States.²

Family-life cycle—respondents were grouped into ten categories ranging from unmarried respondents, through married couples with young or adolescent children, to couples whose children had left home, to elderly respondents living alone.

ANALYSIS

Denominational Identification and Affiliation

The NJPS data indicate that most American Jewish adults continue to identify with one of the major Jewish denominations and to join their synagogues. Half of the respondents reported that they were presently members of a synagogue. This figure underestimates the degree of informal association with synagogues, since membership entails expenses which some individuals are unwilling, or unable, to sustain. Moreover, data to be presented below suggest that many older respondents with grown children, who do not currently belong to synagogues, were previously members. Similarly, some of the younger nonmembers may be expected to join a synagogue as they enter their child-rearing years.

Overall, 86% of the respondents reported a denominational identification. Among synagogue members, 14% identified with Orthodoxy, 49% with Conservative Judaism, 34% with Reform Judaism, and 3% indicated no preference. Among those without a synagogue membership, 7% preferred Orthodoxy, 35% preferred Conservative Judaism, 33% preferred Reform, and 25% had no preference.

² To save space, we dropped the one parent native/one parent foreign-born category.

Given the importance of both synagogue membership and denominational identification, we may obtain a more precise picture of denominational patterns within American Jewry by combining our measures of these two key variables. The cross tabulation of the four-category denominational preference variable and the dichotomous membership variable yields an eight-fold typology of denominational orientations. However, the sample sizes of two of the eight subgroups are too small to justify their inclusion in statistical analyses. Respondents without a denominational identification rarely reported synagogue memberships. Moreover, there are only 174 respondents who identify themselves as Orthodox Jews and who are not members of a synagogue. Therefore, in subsequent tables, we shall report on the six major combinations of denominational identification and affiliation.

Social Characteristics

Table 1 provides data on the demographic and socioeconomic characteristics of individuals identifying and affiliating with each of the three major denominations and on the traits of the unaffiliated or

unidentified. As we shall show later, the ordering of the categories in the table is in terms of their emphasis on Jewish traditions. The Orthodox members represent the highly traditional pole of this dimension, while those without denominational preferences are at the opposite pole. Conservative Judaism is tradition-minded, but, in practice, more flexible in its demands on its members than Orthodoxy, while Reform Judaism is the least traditional of the three denominations.

The sex distributions of the members of most of the six subgroups are similar to that of the overall Jewish adult population. The prominent exception is that of members of Reform synagogues, two-thirds of whom are women. These synagogues would appear to have greater appeal for women because they de-emphasize the traditional religious distinctions between the sexes and are thus closer to the current secular ideal of sexual equality.

Taken together, the data on age, life cycle situation, and generation point to definite differences between the six categories. Over a third of the members of Orthodox synagogues are over sixty, and over half were born abroad. These first generation members include refugees

Table 1. Demographic and Social Characteristics by Denominational Identification and Affiliation of Jewish Adults, NJPS, 1971

from Nazism, as well as aged representatives of the eastern European mass immigration that came to an end in the early 1920s. The third generation is scarcely represented among the Orthodox. The Reform and Conservative denominations are distinctive in their high percentage of married synagogue members with children under 18. Studies of members of synagogues and liberal churches (e.g., Sklare and Greenblum, 1967; Nash, 1968) suggest that many of these individuals are drawn to religious affiliation because of their desire to provide their children with a basic religious identification. Despite these similarities between the Reform and Conservative groups, the affiliates of Reform include more third generation and less foreign-born individuals. Nonmembers who identify with Conservative Judaism are older than both Reform and Conservative members. Such people apparently include more tradition-minded individuals who are not currently active in synagogues. In contrast, those nonmembers who identify with Reform or those who have no denominational identities include a disproportionate number of younger, unmarried adults. Third generation Americans are especially prominent among those expressing no denominational identification.

The strong generational differences between the subgroups reflect the influence of the Americanization process. The least Americanized are more attracted to Orthodoxy, while the most Americanized gravitate toward Reform or express no denominational preference. Conservative Judaism constitutes a middle ground. Multivariate analysis of the relationships between the demographic and denominational variables shows that the sizable life cycle and generational differences between the denominational groups are stable, with controls for the other variables, while the sex and age differences are much smaller.³

Table 1 also provides data on the socioeconomic characteristics of the six subgroups. As the figures for the total sample indicate, American Jewry has become

heavily middle- and upper-middle class. Sixty-two percent of the employed heads of households in the sample work as professionals, managers, or owners. Over a third of all American Jewish adults are college graduates. As a result of the overwhelmingly middle-class character of the American Jewish population, socioeconomic differences between the denominations have become muted, although they have not disappeared. The full tables on educational attainments show that there is a clear gradient; the Orthodox have the lowest levels of formal education, followed by the Conservative nonmembers, the Conservative members, and Reform nonmembers. The Reform members are the most educated subgroup. Similarly, Reform Judaism is distinguished among the three denominations in its ability to attract professionals and the more wealthy segments of American Jewry. The nonidentified individuals and those nonmembers identifying with Reform Jewry are also highly educated and well-off. Only the Orthodox and those without denominational identities include sizable proportions of blue-collar members (16% and 18%, respectively).

In general, then, the demographic and socioeconomic characteristics of the six denominational subgroups correspond to what might have been predicted on the basis of a hypothesis that the denominations may be ordered on a continuum from the least Americanized Orthodox through the Conservatives to the highly Americanized Reform and nonidentified groups. Contrary to this general pattern, however, those without denominational preferences are a highly heterogeneous group, composed of a mixture of the high-status younger adults and the lower status old. The elderly nonidentified appear to be the carriers of the Jewish socialist and secularist tendencies which have all but disappeared from contemporary American Jewish life. Thus, the nonidentified group closely resembles those adults in the general American population who express no religious preference (see Lazerwitz, 1961:575-76).

At the beginning of the twentieth century, Orthodoxy was the dominant form of Judaism for those eastern European

³ Portions of this multivariate analysis appear in Lazerwitz (1978b).

Table 2. Percent Having High Levels of Jewish Identification by Denominational Identification and Affiliation of Jewish Adults, NJPS, 1971

immigrants who had not rejected religion in favor of socialism and freethinking. Reform appealed to the minority of higher status Jews, many of whom were of German origin or descent. Conservative Judaism emerged as the denomination of the second generation descendants of eastern European Jewry. While the denominations today still reflect something of these historic divisions, the differences have been greatly reduced by the socioeconomic achievements of most American Jews and the high proportion of marriages between Jews of different national origins.

Jewish Identification

While socioeconomic differences between the denominations are apparently declining, there are still strong differences between the denominational groupings in their patterns of Jewish identification. Table 2 gives the percentage of each of the subgroups who received high scores on the indices of Jewish identification described above.⁴ The table reveals a clear rank order among the groups; the Orthodox are the most highly identified, followed by Conservative members, Conservative nonmembers, Reform members, Reform nonmembers, while the nonidentified adults rank lowest. The ranking of the members of the denominations on the

dimensions of religious behavior and piety corresponds to the differing emphasis given by the denominational leaders to traditional observance. The pattern, however, also occurs on most of the other dimensions, where official denominational differences are less clear-cut. Thus, the data show that the denominational groupings are, in effect, ranked on their members' degree of ethnic Jewish identification as well as their religious traditionalism. Multivariate analysis suggests that these patterns are the result of a combination of processes of self-selection and influence. Individuals appear to choose the kind of denominational affiliation that most closely resembles the style of Jewish identity they desire for themselves and for their children, and then appear to be influenced by this denominational context.

The most important deviations from the ranking in Table 2 are the high levels of involvement of Reform members in Jewish organizations and the low level of involvement in such organizations among Conservative nonmembers (who include a substantial proportion of older adults).

Table 3 provides illustrative items from four of the indices in order to help illuminate the factors leading to denominational differences and similarities. Keeping a kosher home is a form of religious behavior called for by both Orthodox and Conservative Judaism, but it is optional for Reform Jews. In addition, it is something of a folkway among many first- and second-generation Jews, more of whom are identified with Conservative Judaism.

⁴ The scores for the various indices were ranged from high to low. Then they were divided into three categories in which the number of interviews were as nearly equal as possible. The category with the highest average score is called high-level identity.

Table 3. Illustrative Identity Items by Denominational Identification and Affiliation of Jewish Adults, NJPS, 1971

Identity Indices	Denominational Groups						
	All Adult Sample	Orthodox Member	Conservative Member	Conservative Not Member	Reform Member	Reform Not Member	No Identification
Kosher Home	30%	87%	42%	40%	6%	6%	9%
Frequent Syn. Attendance	13%	51%	24%	3%	13%	2%	1%
Member 2 or More Jewish Org.	24%	39%	40%	14%	41%	7%	5%
Visited Israel	16%	26%	18%	15%	20%	8%	13%

than with Reform. Frequent synagogue attendance is encouraged by all denominations and is a function of a variety of institutionalized influences as well as individual religious feelings. As a result, it varies between denominations and is more characteristic of members than of nonmembers. Membership in Jewish organizations is encouraged by all denominations and is similar among members of all three denominations, but it is less common among nonmembers. This pattern again reminds us that many Reform members are highly active in organized Jewish life despite their tendency to be lower than the members of other denominations in religious observance and background. Since the state of Israel has become a central, unifying symbol of the Jewish people, visiting Israel has become frequent among most subgroups. The less intensely identified and affiliated subgroups also have lower percentages of individuals who have visited Israel.

Secular Correlates of Jewish Identification

A few items in the NJPS permit the examination of the degree to which members of the denominational subgroups differ in attitudes and behavior reaching beyond the realm of Jewish institutions. The first two entries in Table 4 show a strong association between denominational identification and mate-selection patterns. The first entry shows that most couples had the same denominational identification when they originally met. Moreover, men with a denominational identification rarely met and married women with no identification. The second

row of the table shows the percentage of husbands who reported that their wives were not Jewish when they originally met. Intermarriage percentages are equally low for Orthodox and Conservative men, are roughly double for men identifying with Reform, and jump to 17% for those having no identification. These data make it clear that many of the Jewish men expressing no denominational preference are at the margins of the organized Jewish community.

The last two entries in Table 4 provide some indication of the attitudes and involvement of the respondents in the non-Jewish, general community. These data show that Reform members and nonmembers are more liberal politically than individuals associated with Orthodox and Conservative Judaism. Although this tendency partially reflects the higher socioeconomic status of the Reform Jews, multivariate analysis shows that it is not fully accounted for by this factor. Service to the general community and political liberalism are strong traditions within Reform Jewish life and historically have played an important part in the denomination's ideology. Despite their similarities to Reform, individuals lacking denominational identification are much less active in general community voluntary associations. In sum, the data show clearly that aspects of secular behavior and attitudes are strongly associated with denominational identification among American Jews.

CONCLUSIONS

Our intention in this report has been to provide a basic profile of the social and religious characteristics of individuals af-

Table 4. Secular Correlates of Denominational Identification and Affiliation of Jewish Adults, NJPS, 1971

Characteristics	Denominational Groups								
	All Adult Sample	Orthodox		Conservative		Reform		No Identification	
		All	Member Only	All	Member Only	All	Member Only		
									Member Only
% Men Marry within Denomination	56%	65%	—	67%	—	—	62%	—	55%
% Men Marry Non-Jewish Women	7%	3%	—	4%	—	—	9%	—	17%
% High Gen. Vol. Assoc.	29%	—	19	—	32%	—	50%	37%	20%

filiating and identifying with Jewish denominations or having no denominational identification. We have omitted the presentation of conventional significance tests because they would add little to the results. The consistency of the patterns shown here, the large sample size, and the persistence of the major differences between the denominations when controls are introduced in multivariate analyses (e.g., Lazerwitz, 1978b) were sufficient to convince us that the patterns reported are unlikely to have been due to chance variations.⁵

In concluding, we shall briefly review our findings on Jewish denominational patterns. Then we shall compare and contrast Jewish and Protestant denominational differentiation and make some observations on the durability of the denominational pattern within American society.

Are the classic "social sources" of Jewish denominationalism disappearing with the increasing Americanization of the American Jewish community? It has been found that the historic differences between the denominations in terms of socioeconomic factors have declined considerably. While differences of education, occupation, and income do still appear among the subgroups, such differences are small and may be expected to decline even further. However, generations in the United States, a clear reflection of Americanization, are still a substantial source of distinction among the groups.

Differences in religious behavior and belief are strong and appear to be stable. These differences are not accounted for by the social and demographic characteristics of those belonging to, or identifying with the various denominations.

⁵ Some comment about significance testing is in order. First, this survey's complex, multistate, clustered sample data require special sampling error treatment which is presented in detail in Lazerwitz (1974). In general, the sample design effect (the blow-up over simple random sampling,) is 3.5. Anyone who wants to do significance testing with any of the percentages of this survey needs to multiply simple random sampling errors by 3.5 before plugging them into any significance testing equation.

Rather, denominational identification and affiliation with a synagogue are strongly associated with variations in Jewish behavior and orientations. At one pole are the Orthodox Jews, a small but active minority within American Jewry, who retain the highest levels of traditional Jewish behavior and ingroup involvement. At the other extreme are Jews without any denominational identification who rarely affiliate with Jewish institutions and ignore most Jewish traditions. The Conservative and Reform Jews maintain a position between these two poles; the Conservatives are nearer to the Orthodox pattern and the Reform are closer to that of the unidentified.

Our data also show that within the Jewish community, where religious and ethnic orientations are deeply intertwined, denominational identification and affiliation do have important secular correlates. The NJPS provides evidence on marital patterns, political attitudes, and membership in general community organizations, while other possible correlates are as yet unexplored. The Orthodox are characterized by greater political conservatism and greater involvement in the Jewish community than in the general, non-Jewish, community. Reform and Conservative Jews more typically appear to combine lower levels of Jewish involvement with more political liberalism and active participation in the general community. Jews without a denominational identification are less active in both Jewish and non-Jewish associations. This pattern may reflect their preference for more individualistic, and unconventional, sources of satisfaction and belonging.

Comparisons with Protestantism

The evidence from NJPS supports the assertions of Glock and Stark (1955), Greeley (1972), and others that America continues to be a "denominational society." Within American Jewry, as within American Protestantism (Glock and Stark, 1965; Stark and Glock, 1968) congregants continue to be divided into religiously distinctive camps. In Judaism, the lines of ideological division and the denominational structure closely resemble

those found in Protestantism. Among both Jews and Protestants there are clear divisions between an inactive sector, liberals, moderates, and conservatives. Moreover, in both religious groups the more conservative denominations are closer to a sectarian position in their social structure and ideology. These structural and ideological parallels have their counterpart in some noteworthy similarities at the level of individual behavior. The NJPS data, like the Lazerwitz (1973a) study of Protestants and Jews in Chicago, point to parallels between the levels of traditional religious behavior among Orthodox Jews and fundamentalist Protestants, among Conservative Jews and Protestants preferring Conservative denominations, among Reform Jews and liberal Protestants, and among those Jews and Protestants with no denominational preferences. The Chicago study also found similarities in the involvement of Reform Jews and liberal Protestants in general community organizations, and in their greater political liberalism. However, the actual levels of liberalism among all Jews, apart from the Orthodox, exceeded the Protestant levels.

Denominational identification and membership have strong associations with aspects of Jewish life that are above and beyond Jewish institutional boundaries. Can the same conclusion be drawn with respect to Protestant denominations? The search for such consequences of Protestant denominationalism has yielded little in the way of consistent results (Bouma, 1973; Rojek, 1973; Schuman, 1971; Winter, 1974). Perhaps the inability of researchers to find consistent and substantial secular consequences of involvement in Protestant denominations stems from their tendency to ignore differences between church members and nonmembers and the frequent absence of data on those who consider themselves Protestants but have no denominational preference. On the other hand, given the intensity and resourcefulness with which the search has been pursued, it may well be that there are quite limited Protestant denominational consequences in the political and economic areas. In contrast, the dual status of American Jewry as a minority religious-ethnic group heightens the likelihood that

differences in Jewish loyalty and belief will produce political and economic correlates. It seems more likely that there are direct effects of Protestant denominational orientations on values and behavior which are especially subject to individual discretion and less institutionally regulated, such as patterns of family life and use of leisure time.

The NJPS findings reinforce the position that socioeconomic status, ethnicity, and degree of urbanization or Americanization, now play, or soon will play, a less prominent role in sustaining denominational differences than in the past. While race and historical regional differences still contribute to Protestant denominationalism, the end of mass immigration, the urbanization of the United States, and the predominantly middle-class character of Protestant Americans (Anderson, 1970) and Jews indicate that the classic social sources of denominationalism are drying up. Instead, among both Jews and Protestants, religious and ethnic orientations are becoming increasingly independent of their original social correlates. Moreover, the tendency of increasing numbers of Jews and Protestants to eschew affiliation with organized religion may sharpen denominational differences rather than weakening them further. As the least committed drift away from religious affiliation, they will leave behind those for whom matters of belief and behavior have the most significance. Should these trends within the American Jewish and Protestant communities continue, we would anticipate the emergence of a denominationalism based more on variations of belief and religious style than on social and economic divisions.

COMMENTS

ORGANIZATIONAL THEORY AND CULTURAL INTRUSIONS INTO ORGANIZATIONS

(COMMENT ON LINCOLN, OLSON, AND
HANADA, ASR DECEMBER, 1978)*

Lincoln, Olson, and Hanada (1978) state that "rationalistic theories of organizational action and adaptation are at best incomplete." Their methodologically elegant research on Japanese firms located in the United States tantalizingly looks at the intrusion of the Japanese culture into the structure and operating processes of these firms. However, their results about the relevance of Japanese culture are inconclusive. Japanese culture appears to have clear effect on specialization, but it has unclear effect on other dimensions of organizational structure, such as centralization, formalization, and hierarchical ranking. Perhaps these findings are due to inadequacies in the conceptual model employed, which are the result of weaknesses in the theories of organizational action which the authors themselves note.

It seems that the authors' point about the inadequacies of rationalistic theories needs to be, and can be, clarified considerably. Not only do we need to recognize that "organizations incorporate as permanent features of their operations blueprints of the habits, customs, and values of their members and the larger population in which they are imbedded," but also we need to develop models for just how these intrusions from the surrounding cultures actually coexist with other structural dimensions of organizations. What sort of blendings occur? What mechanisms control the pervasiveness of the external and, sometimes alien, cultural patterns within an organization?

Some years ago I tried to develop such a model by pointing to strategically placed areas of localized discretion (local autonomy) that exist within organizations (Katz, 1968; 1976). In contrast to models that emphasize control—including hierarchy, centralization-decentralization—one can conceive of organizations as mosaics of localized and coexisting autonomy. There are several distinctive forms of autonomy; autonomy is clearly locatable; autonomy has definite limits. For instance, executives have certain forms of

decision-making autonomy; technical specialists have certain forms of decision-making autonomy; assembly-line workers, too, have certain forms of autonomy. These forms of autonomy are based on the tasks that need to be done and the goals that are being pursued. But they also are based on the environment in which the organization exists and to which it adapts. For example, it has long been known that assembly-line workers can bring into their daily work activities many of the thought-ways of their external life. They have the autonomy to do this. Conversely, executives export the thought-ways of the business into their community activities. Their autonomy facilitates this. Such culture *import* and *export* processes are part of the adaptive process of organizations. They tend to be built into the structural arrangements that make up an organization.

Structural arrangements may include countervailing forces. For instance: (1) A physician accepts close control over his or her salary and clinical work schedule by a hospital's administration in return for much autonomy to carry out research. The research may involve great attunement to the "outside" world of research and minimal attunement to some of the hospital's needs for immediate practical results. (2) Assembly-line workers' autonomy to think and talk about outside interests—sports, sex, family—is counterbalanced by their disfranchisement from the administrative culture of the organization in which they are employed.

In short, organizations are not merely open systems in the sense that the outside culture intrudes (and it, in turn, extrudes some of its culture into its environment). They are open systems of a special sort. To be sure, they permit the outside culture to have entry into the organization. But they have definite ways of channeling this intrusion, of limiting it, of harnessing it, and of adapting to it in patterned ways. All this is facilitated by the manner in which autonomy is suffused throughout the structure of organizations.

It seems that such a model could help clarify "Japaneseness" in the factories studied by Lincoln, Olson, and Hanada. It would help focus on how Japanese cultural patterns are channeled and just how they are amalgamated with American patterns. This, in turn, would be useful for developing more adequate models for intercultural adaptations. When organizations sink roots in a different culture from the one in which they were initially nurtured,

REPLY TO KATZ*

Katz argues that students of cultural influences on organizational structures should adopt a model of organizations which explicitly recognizes that employees possess the autonomy to "import" and "export" cultural beliefs and values across organizational boundaries. We do not take issue with this view but neither do we find it illuminating. To say that employees "... bring into their daily work activities many of the thought-ways of their external life" because "they have the autonomy to do this" is tantamount to saying that they do it because they can do it. We doubt that one has progressed very far toward an explanation of cultural influences by merely acknowledging that organizational constraints are not so severe that cultural phenomena are invariably barred from finding their way into organizational processes.

If there is any real point of contention between Katz and ourselves it hinges on his implication that our neglect of the autonomy question accounts for our failure to find cultural effects on certain structural dimensions. This perplexes us. Unless he means that we might have included some measure of autonomy in our regressions or otherwise respecified them in conformity with a "culture-via-autonomy" model, it is hard for us to grasp the sense in which our results might have proved different. That Katz did not in fact propose such concrete changes in our research strategy suggests that no such carefully considered matters motivated this criticism.

WHOSE STATUS COUNTS?

(COMMENT ON TITTLE, VILLEMEZ, AND SMITH, ASR OCTOBER, 1978)*

In their splendid article, Tittle et al. (1978) performed a considerable service by their painstaking demonstration that the large empirical literature fails to demonstrate any important correlation between class and delinquency. I have been reporting this lack of a relationship in my textbooks throughout this decade (Stark, 1973; 1975; forthcoming). And, I have often been criticized for doing so. I may now cite a quite definitive work in place of my own, far less systematic, reading of the evidence.

However, as I have pointed out in the same textbooks, there is a very important way in which it can still be said that class has a considerable negative impact on delinquency. Since writing in lower division textbooks does not inform a professional audience, I offer this brief comment on Tittle et al. in order to extend their discussion and to clarify the theoretical meaning of the lack of a class-delinquency relationship in the literature.

In the studies in question, social class or SES is measured by the *family* status of juveniles. The assumption is made that children are of the same social class as their parents. However, we know from studies of status attainment (cf. Blau and Duncan, 1967) that, at least in the United States, the majority of adults are not of the same status as their parents—the majority move upwards or downwards from their status of origin. This raises important questions. At what age does mobility begin? At what age has the mobility process reached the point where status of origin is an inaccurate measure of current status? For practical reasons we usually have ignored these questions and have waited until people have completed their education and found their own niche in the labor force before we have assigned them their own status, as distinct from the status of their family. Yet, it will be obvious that the process by which young people achieve educations and find a position in the labor force begins at a much younger age. Indeed, it easily is seen that the position young people have attained in teenage society—especially in the status system of the school—is a very strong predictor of where they will end up as adults. People who are "succeeding" in high school usually add to this success later. People near the bottom of the high school status system tend to remain near the bottom in later life. Indeed, for the majority

* Direct all communications to: Rodney Stark; Department of Sociology; University of Washington; Seattle, WA 98195.

of school drop-outs, the status attainment process virtually ends during their teens.

To these considerations, add the fact that the delinquency research uniformly finds that *position in teenage society is very strongly, negatively related to delinquency*. The better a person is doing in school, the higher a person stands among his or her peers, the less likely that person is to commit delinquent acts (cf. Hirschi, 1969). If we assign teenagers a class position of their *own*, based on their standing relative to their peers, then we find a powerful negative relationship between class and delinquency. It is only when we assign young people a class position on the basis of their parents' status that we find little or no relationship.

Thus, two things can be (and appear to be) true at the same time. (1) Young people from wealthy homes are about as likely as young people from poor homes to commit acts of delinquency. (2) A young person's own status is strongly related to delinquency. Both can be true because family status is so weakly related to the status of offspring.

This raises the possibility that empirical suggestions of an historic decline in the association between family status and delinquency might reflect a weakening of the association between status attainment and status of origin as well as the reforms in the justice system mentioned by Tittle et al. In any event, theories predicting a relationship between class and delinquency (for example, strain and control theories) are not called into question by the lack of correlation between family status and delinquency. The contradiction between these theories and the data evaporates when we recognize that family status is not adequate as a proxy variable for the status of teenagers.

Having added these points to the discussion, I should like to congratulate Tittle et al. for their careful and imaginative scholarship.

REPLY TO STARK*

We appreciate the kind remarks of Professor Stark, and are pleased that our empirical research has confirmed some of his notions. He has provided an additional caveat to those we suggest, which, of course, adds an element of wise reserve. Nevertheless, it appears to us that his effort to "rescue" the class/delinquency relationship is likely to create more confusion than clarification. Therefore, we feel compelled to point out some problems with his argument.

His central point is simply that the proper data for ascertaining the social class of teenagers is not the social class of their families, but rather their positions in a high school status hierarchy. With social class thus measured, he argues, the class/criminality relationship is empirically supported. Note the following, however:

(1) Our focus was the general relationship between illegal behavior and social class. Professor Stark seems to assume that the analysis deals only with juveniles since he overlooks the inclusion of adult studies as well as the separate figures for adults and juveniles which show similar patterns. It would be difficult to apply his suggested explanation to adults.

(2) Stark cites Blau and Duncan to the point that the status of most persons ultimately differs from their status of origin, and he concludes from this that origin is a poor measure of class for juveniles. But apart from the problem of determining when mobility begins, Blau and Duncan also show that most completed intergenerational mobility in the United States is short-distance mobility. The average move is so small that it would probably be inconsequential for class/crime theories.

(3) Stark's contention that position in a high school status hierarchy is a predictor of future status superior to that of family of origin is dubious, both conceptually and empirically. It is hard to imagine that the attributes positively evaluated by teenagers are those crucial to fu-

We are grateful to John Johnstone for his comments on a draft of this reply.

ture success, and we know of no studies which directly examine that relationship controlling for class of origin. Position in teenage society has been shown to be a good predictor of expected future status, but that is not the same thing.

(4) We do not dispute that position in any evaluative hierarchy could be negatively related to deviance; the self-esteem literature suggests as much. Indeed, a full theory about delinquency built around Stark's notion would be a welcome addition to the field. We do dispute, however, the use of teenage status as a measure of social class, particularly as social class is understood from theories which lead to a class/criminality hypothesis. Such usage does violence to the concept of class and class effects. Granted, class of origin may once have been a stronger predictor of status in high school than it is now. And it may be that high school status is the best independent predictor of delinquency (although we doubt it). But in our opinion, neither of these really has anything to do with the class/delinquency relationship because high school status systems are too transitory and varied from school to school to embody things implied by theories about social class and criminality.

Stark's commentary does bring to mind an important issue about delinquency and social class that is raised by our findings. There does appear to be an empirical relationship between class origin and academic performance in high school. There also seems to be a consistent and strong association between academic perform-

ance and delinquency (although neither of these apparent relationships has been subjected to rigorous comparative analysis like that we used in our examination of the class/criminality relationship). Therefore it should follow that there would be a strong class origin/delinquency association, but of course, our paper shows that in general such a relationship has not been demonstrated. Either the origin/performance or the performance/delinquency association is in error or some rather complex interactions are involved which need to be sorted out empirically. But this problem cannot be solved by merely relabelling position in a high school status system as social class.

In summary, we think the attempt to reconcile our findings with others about delinquency is a worthy enterprise. But Stark's assumptions contradict some well-established precepts from the field of stratification.

Again, we appreciate Professor Stark's credible attempt to solve a knotty problem raised by our results. We are intrigued with the puzzle ourselves, and we invite others to join in the effort to figure out what is going on.

AMERICAN SOCIOLOGICAL REVIEW

THE STRUCTURE OF A NATIONAL ELITE NETWORK*

GWEN MOORE

State University of New York, Brockport

American Sociological Review 1979, Vol. 44 (October):673-692

This paper addresses a long-disputed issue: the degree of integration among political elites in the United States. This issue is examined through an investigation of the structure of an elite interaction network as revealed by recently developed procedures for network analysis. The data, taken from the American Leadership Study conducted by the Bureau of Applied Social Research in 1971 and 1972, consist of interviews with 545 leaders of major political, economic and social institutions. The study's wide institutional representation, sociometric data, and focus on major issues of the early 1970s make it virtually unique for examining elite integration.

The structure of national elite groups, and particularly the degree to which they are integrated, is a critical issue in political sociology and political science. While considerable integration of elites was generally assumed by the classical elite theorists, Pareto, Mosca and Michels, recent investigators have disagreed strongly about the relative amount, causes and consequences of elite integration in western, industrialized societies.

In the United States a lengthy debate over the structure of power and influence at the national level has centered on the degree to which this structure is unified or diversified. Ruling class and power elite

theorists¹ such as Mills and Domhoff find a considerable amount of integration, with various bases, in the national power structure. According to Mills (1956:292):

The conception of the power elite and of its unity rests upon the corresponding developments and the coincidence of interests among economic, political, and military organizations. It also rests upon the similarity of origins and outlook, and the social and personal intermingling of the top circles from each of these dominant hierarchies.

The existence of a broad, inclusive network of powerful persons with similar social origins, in different institutions, is then one important feature of this view of the power structure.

Pluralists find little integration among elites in diverse sectors. For example, in drawing conclusions from his study of private power and American government, McConnell (1966:339) writes:

The first conclusion that emerges from the present analysis and survey is that a sub-

* Direct all communications to: Gwen Moore; Dept. of Sociology; Uris Hall; Cornell University; Ithaca, NY 14853.

An earlier version of this paper was presented at the 1978 meetings of the American Sociological Association, San Francisco. The work reported here, part of the American Leadership Study and the Comparative Study of National Leaders' Networks, was supported by NIMH grant MH17919-01 and National Science Foundation grant GS35828X. I am grateful to Allen H. Barton, G. William Domhoff, Charles Kadushin, Edward W. Lehman, Herbert Menzel, Beth Mintz, R. Wayne Parsons, Carol H. Weiss, J. Allen Whitt and Dennis H. Wrong for helpful comments on previous drafts of the paper. I would especially like to thank Richard D. Alba for valuable assistance with the data analysis and suggestions on earlier versions of this work.

¹ Recent empirical work on the structure of power in the United States has often combined elements of classical elitist and Marxist theories (e.g., Mills, 1956; Domhoff, 1967; 1970; Miliband, 1969). While important differences distinguish these theoretical positions (Alford, 1975; Whitt, 1979), contemporary scholars in both traditions usually agree that a unified ruling elite, with strong ties to an upper social class, exists in the United States.

stantial part of the government in the United States has come under the influence and control of narrowly based and largely autonomous elites. These elites do not act cohesively with each other on many issues. They do not "rule" in the sense of commanding the entire nation. Quite the contrary, they tend to pursue a policy of noninvolvement in the large issues of statesmanship, save where such issues touch their own particular concerns.

Pluralists argue that each elite group is distinct and narrowly based, with influence confined to the issues most relevant to its membership (Rose, 1967; Dahl, 1961; Polsby, 1963). Elites are seen as fragmented rather than integrated since each is involved primarily with its own relatively narrow concerns and constituencies (Keller, 1963; Aron, 1966).

The study reported here assesses the extent of integration in a network of political elites in the United States.² The concept of political elite integration has several dimensions including, at least, social homogeneity, value consensus and personal interaction (Putnam, 1976: 107). Social homogeneity, the extent to which elites share class and status origins and common experiences such as attendance at exclusive private schools, is usually seen as fostering integration (Mills, 1956; Domhoff, 1967; Baltzell, 1964; Dye, 1976). For example, Porter (1965:528), writing about Canadian elites, concludes:

Even if they have never met before, when they come into contact with one another as members of elites their identity of interests stemming from their common social characteristics and experiences facilitates communication.

² The term *political elite* as used here refers to persons who by virtue of their institutional positions have a high potential to influence national policy making. Thus, the political elite consists not only of high-ranking government officials but also of top position holders in large organizations in the private sector including major corporations, labor unions and other organized interest groups which attempt to influence government policy. In a similar definition, Parry (1969:13) includes in the political elite politicians, government officials and the leaders of various interest groups which attempt to influence the allocation of values in society. For stylistic variation, I sometimes use the terms *leaders*, *influentials* or simply *elites* to refer to political elites.

The degree to which leaders agree on political beliefs, both specific public policies and broad ideological orientations, is often used as a measure of value consensus (e.g., Putnam, 1976; Prewitt and Stone, 1973; McClosky, 1964; Barton, 1974; Higley et al., 1976). Agreement among elites at least on the "rules of the game" usually is considered essential not only to integration but also to political stability (Prewitt and Stone, 1973; Field and Higley, 1973).

Personal interaction among elites is probably the crucial dimension of integration. Giddens (1975:120), for instance, defines an integrated elite as one in which members of different elite groups frequently interact as acquaintances, friends or kin. He contends that a highly integrated elite is likely to exhibit both solidarity and relatively little conflict. Many others (e.g., Bonilla, 1970; Mills, 1956; Domhoff, 1967; Kadushin, 1968) see interpersonal contact among political elites in diverse positions as essential for the development and maintenance of integration at the national level. In a common view, the social organization which is a prerequisite for integration depends in part on a network structured to facilitate interaction and communication among persons in high-level positions in all major institutions. Without extensive connections among persons in different institutions, value consensus could not be achieved or maintained, and the development of solidarity could not occur since it requires trust and familiarity. Elite groups in different sectors would then remain largely encapsulated and fragmented. The investigation of the structure of elite interaction networks thus is a central concern in the assessment of elite integration.

While, with the exception of Hunter's (1959) *Top Leadership USA*, no previous studies of interaction among elites in diverse positions in the United States have been reported, formal connections, such as common membership in organizations or social groups, often have been used to analyze interconnections among elites. There has been much recent attention to tracing interlocking directorates in major U.S. corporations (Levine, 1972; Allen, 1974; Sonquist and Koenig, 1975; U.S.

Congress, 1978). The implicit assumption in such studies is usually, according to Allen (1974:393), that: "... interlocking directorates serve as at least partial evidence that contemporary industrial society is dominated by a coherent and cohesive economic elite."

These ties are thus seen as fostering integration, cohesiveness and perhaps consensus within the business community. Sonquist and Koenig (1975:199) argue that:

Being a member of a network of individuals in the business world outside of one's "home" company provides common life experiences, common views of reality, definitions of what is right and wrong, and opportunities to validate one's beliefs about social and economic issues and the goals that one ought to pursue with respect to them.

Also:

A consequence of multiple participation is the maintenance of well-oiled communication channels.

Many social scientists have examined sociometric ties among elites in individual communities or groups (e.g., Laumann and Pappi, 1973; 1976; Laumann et al., 1977; Kadushin, 1974; Presthus, 1974), but such data rarely have been gathered for major groups at the national level (but see Bonilla, 1970; Barton et al., 1973; Higley et al., 1976; Higley et al., 1979; and Denitch, forthcoming). The American Leadership Study, a survey of top position holders in powerful American institutions, which includes data on interpersonal contacts, offers a unique opportunity to examine the extent of integration or fragmentation among political elites in the United States.

I begin with an examination of the structure of an elite interaction network, with particular interest in whether or not it contains many distinct groups individually formed around narrow issue concerns or, rather, a few large and inclusive groups, each including varying constituencies and concerns. This examination locates one large, cohesive group of leaders, representing all major institutions and issue areas, which serves to integrate the network. Given this finding of integration of American leaders in a large "central cir-

cle," two additional issues are addressed. In order to validate the method used, i.e., to be certain that this circle contains the most powerful or influential elites, the members of this central circle are compared with others in similar top-level positions to see if circle members are more influential in ways other than circle membership. Then, the relationship between social origins and current affiliations and membership in the central circle is examined to see if high status origins or influential current affiliations (beyond primary institutional position) are advantageous in achieving connections to this group. Thus, this analysis not only examines the extent of integration but also the social bases for the integration that is found.

RESEARCH DESIGN

The data used are taken from the American Leadership Study, a survey of 545 top position holders in key institutions in American society conducted in 1971-72 by the Bureau of Applied Social Research, Columbia University. Through personal interviews, information was gathered on respondents' policy influencing and policy making activities on major national issues. Extensive attitude and social background data also were collected. The study's wide institutional representation, collection of sociometric data and focus on major issues of the time make it well-suited for evaluating elite integration.

The sample is drawn from persons in the top positions in ten institutional sectors assumed to exercise power in American society. The institutions and positions sampled in each are shown in Table 1. The leaders in the positional sample were asked to name other persons with whom they interact or who they felt were currently influential among leaders in the United States. From the responses to these questions a snowball sample of 61 "opinion-leaders" (Katz and Lazarsfeld, 1955; Kadushin, 1968) was chosen to correct for important omissions in the positional sample. Most persons in the snowball or reputational sample were in one of the ten positional sectors, especially Congress and the media; a few were not; these

Table 1. American Leadership Sample Sectors

Sector	Position
Congress	Senators; members of House of Representatives in following categories: chairman and ranking minority members of all House committees; all members of the Rules, Appropriations and Ways and Means Committees; 50% of sample was drawn from Senate, remainder from House.
Federal Administration— Political Appointees Civil Service	Secretaries, assistant secretaries, and general counsel of cabinet departments; heads and deputy heads of independent agencies. Two highest civil service grades from all cabinet departments and independent agencies.
Industrial Corporation	Fortune 500 largest industrial corporations in 1969.
Nonindustrial Corporation	Fortune 300 largest nonindustrial corporations in 1969; 50% of sample is from banks and insurance companies, remainder from utilities, transportation and nonindustrial corporations.
Holders of Large Fortunes	Holders of fortunes worth at least \$100 million.
Labor Union	Presidents of unions with at least 50,000 members; officials of the AFL-CIO.
Political Party	Members of Democratic and Republican National Committees; state and city chairpersons of these parties.
Voluntary Organization	Elected head and full-time director of various public affairs organizations including professional societies, farmers' organizations, women's groups, religious organizations, civil rights organizations, business groups and others.
Media	Editors of largest circulation newspapers and public affairs periodicals; syndicated columnists and news executives; broadcasters and commentators of national networks.

include academics, White House staff, governors and mayors. In light of the debate over methods for identifying influential or powerful individuals, it is worth noting that in this case the same persons frequently were identified by the positional and reputational (snowball) techniques. Depending on how many respondents were added in the snowball phase in a given sector, 50 to 60 persons were interviewed in each positional sector.³ (Because of similarities in function, I combine the industrial corporations, nonindustrial corporations and holders of large fortunes in a sector called business. Likewise, members of the White House staff are analyzed as part of the political appointees' sector.) The overall completion rate for the interviews is just over 70% (see Barton et al., n.d., for a more complete description of the sample).

Each respondent was asked to choose one national issue on which he or she most actively had attempted to influence national policy or inform public opinion in the past few years. The major part of the interview then focused on activities and contacts concerning this issue. A wide

variety of issues was chosen, most of which were related to the individual's formal position. For example, business leaders often decried the recent institution of price controls, while labor leaders discussed their opposition to wage controls. While respondents usually discussed narrow issues (e.g., prices in the steel industry, U.S. policy toward a specific country), when similar issue concerns were collapsed into more general categories, three major issue areas emerged. The most frequently discussed issue area was the economy (28.6%), a prime concern of government, business and labor at that time. Wage and price controls were instituted by President Nixon during the interviewing period and, as noted, many respondents chose the topic of controls as their issue focus. Other common issues were foreign policy (17.2%), especially the war in Southeast Asia, and a variety of social policy issues (26.6%), including poverty, race relations and urban problems. Less frequently discussed issues include the environment, law and order, and government reform. A series of sociometric questions referring to the respondent's major issue of activity was asked. These questions dealt with both personal contacts (e.g., "Of the various people you

³ The number of respondents in each sector is shown in Table 4.

have talked with about this issue, who had the most useful and interesting things to say?"⁴) and reputation for influence (e.g., "Who has the greatest influence among leading Americans on this issue?"). Respondents were allowed an unlimited number of responses to each sociometric question. The network analyzed here is constructed only from those nominations involving direct personal contact; nominations referring to reputation for influence are used subsequently for purposes of validation. A variety of questions on personal contacts was used to elicit each respondents' interaction partners in various sectors and situations within the context of his or her chosen issue area. In the analysis nominations from all questions are combined to yield each person's interpersonal connections in this limited issue context.

The interpersonal network in these data, resulting from interaction related to a specific issue for each respondent, generally reflects informal discussions or day-to-day interaction on these issues. This network is, of course, not identical with networks formed in other contexts and does not include all personal connections which exist among the individuals in this study. Undoubtedly, many persons in this network who are personally acquainted or who interact socially did not report that fact here (see Bonilla,

1970:150; also Barton, n.d.). Also, let me note that given the focus on specific issues, this network does not reflect issues which remain potential or undiscussed (Bachrach and Baratz, 1963; Lukes, 1974).

Several aspects of the procedure for collecting the sociometric data need to be pointed out so that their possible effects on subsequent findings may be understood. The first and most important is the snowball sampling method itself. It is not feasible to carry out an elite study in a large differentiated society like the United States by interviewing all members of elite groups. But since relations between members of a *sample* may be few and scattered, a study which intends to examine individuals' positions within an elite network must supplement any initial random sample. It is necessary to pursue chains of linkages originating in the initial sample to gain some view of the network structure and snowball sampling is one method of pursuit (see Erickson, 1979; Kadushin, 1968). A snowball sample gathers individuals through interviews with those named (in this case, frequently named) by members of the original sample. The snowball phase may consist of a single wave, following only the direct links of the original sample, as was done here, or a larger number of waves, successively following links of each previous wave of the snowball sample.

The mere fact that links are traced by the snowball sampling method does not lead to the artifactual emergence of circles and cliques in the network data, since the chains are naturally occurring. In this case, in any event, chains are followed for only one link, rather than pursued until a particular connection is made, as in the "small world" method. Clearly, such a procedure does not guarantee finding a strongly interconnected network. Even were the chains traced further, a network structure consisting of small, disconnected groups rather than a large inclusive one should emerge from the data if the pluralist conception of fragmented elites is accurate.

Also, the wide variety of issue areas discussed makes a finding of small, issue-based groups more likely than one of

⁴ Other interaction questions are: Have you drafted proposals or written memoranda recommending policies to follow on this issue? To whom? Have you talked with individual legislators about your policy position on this issue? With whom? Have you talked with federal officials about your policy position on this issue? Which people? Have you tried to get people that you know to support or oppose legislation on this issue? Who? An additional six questions were asked of snowball respondents: Have you talked with (substitute the phrases: people in business and finance, labor leaders, other interest group leaders, mass media people, people at the political party organizations, people in the White House) about your policy position on this issue? Also, the following questions about contact with organizations were asked of all respondents, and nominations of individuals offered in response to them were included among the interaction nominations: Have you testified before legislative committees about this issue? Have you worked with an interest group or organization trying to influence public policy on this issue? Have you worked within your own organization on this issue?

a large, inclusive group because only contacts resulting from involvement in a single issue area were elicited. Had respondents been asked about interaction on several issues or more generally, each individual's named contacts would probably have represented a broader range of institutions, thereby making a finding of small, specialized groups less likely. However, this bias is counterbalanced by sociometric questions which specifically ask about contacts with persons in the federal political sectors, increasing the likelihood of finding a large, generalized group. These questions lead to the overrepresentation in the nominations of members of Congress and political appointees, who, because of their frequent involvement in a variety of issues, often are connected to persons with diverse positions and concerns.

The analysis of these sociometric data utilizes a procedure developed by Alba (1972; 1973) which is well-suited for evaluating network integration since it identifies the more cohesive parts of networks. The cohesive regions are those in which dense interconnections exist among sets of individuals. These connections may be face-to-face, as in cliques, or through short chains of interaction, as in social circles (Kadushin, 1966; 1968; Alba and Moore, 1978). Since cliques are generally face-to-face groups, they tend to be relatively small. Social circles, on the other hand, may be much larger.

The identification of social circles among political elites in the U.S. seems an appropriate base for studying the extent of their integration. To begin with, given the large size of the totality of American political elites, they could not be integrated through cliques, since these are generally quite small. In addition, social circles have other characteristics making them suitable for the study of political elite integration. Not only are they cohesive groups whose members can easily communicate and interact with one another, albeit often indirectly, but they are also usually informal groups, lacking defined leadership, whose members are drawn together by similar interests and concerns (Kadushin, 1968:692). Thus, positing a social circle as the basis for elite

integration does not require that its boundaries be visible to its members. Finally, individuals belonging to large, diverse social circles are likely to be more influential than those with more circumscribed connections because they serve as links in elite circles joining persons in high-level positions in a variety of institutions.

If circles can be identified in a network, the nature of their memberships and their relations to each other and the rest of the network are critical for assessing the extent of the network's integration. The existence of cohesive circles (or cliques) does not, in itself, guarantee that the network as a whole is integrated. By definition, an integrated network is one in which "communications" of various kinds can spread easily from one of its parts to another. Crucial then for integration are the ways in which a network's different parts are joined together. One mechanism making for integration is the existence of large circles with diverse memberships, thus drawing together individuals from different institutional areas in a society. Another is the existence of linkages joining these circles to a variety of small, otherwise disconnected cliques and circles. These linkages may take the form of overlapping memberships or direct ties between the members of different circles and cliques. By contrast, evidence of fragmentation is the existence of small, narrowly based circles or cliques which are widely dispersed, i.e., distant from each other in the network.

In specific terms, the procedure for identifying cohesive groups begins with the network of relations formed by all interaction nominations made by sample members. These relations are treated as symmetric since they represent direct communication (see Laumann and Pappi, 1973, and Laumann et al., 1977, for a similar assumption). Also, the intent to locate individuals in their interaction context or social milieu in a large network makes the identities of their connections more critical than the reciprocity or lack of it in reported connections. (From a practical point of view, symmetricizing connections allows nonsample members to be drawn into the network, an important advantage in elite studies since it is

impossible to interview all potential respondents.) Thus a link between any pair of persons is defined as present if at least one individual in the pair reports talking to the other and absent if neither named the other as an interaction partner. The network formed in this way is not limited to respondents but also includes persons outside of the sample who were named as interaction partners by at least two sample members and thus form a link between them. As a result, the full network is composed of 396 persons outside of the sample and 480 of the 545 sample members. The remaining 65 individuals in the sample are isolates who are connected to none of the persons in the network. All of the 876 persons in this network are connected through chains,⁵ but the network is not dense; of the possible direct connections less than 1% (.7%) exist.

Then, cliques and circles are identified in this network. The first step is to identify cliques, i.e., tightly knit, face-to-face groups, which are defined for my purposes as groups of at least three persons, each of whom is directly connected to all of the others. Such groups are known in graph theory as maximal complete subgraphs (Harary, 1969) and an algorithm for locating these subgraphs identified 442 such completely connected groups. The next step is to use these cliques to identify the circles in the network. Circles can be viewed as webs of intricately interlaced cliques, in which indirect communication is facilitated because circle members are also members of these highly overlapping cliques (Alba and Moore, 1978). Thus, circles can be identified by merging highly overlapping cliques. One stage in this merging process was to combine groups, i.e., cliques or emerging circles, when they differed by only one member. When all such possible merges were exhausted, 46 groups remained. However, many of these still overlapped greatly, with the membership of some almost entirely included in the membership of others. When two-thirds or more of the members of a

smaller group were also members of a larger group, the two groups were merged. Thirty-two cliques and circles emerged as the end product of this procedure.⁶

Membership in such cliques and circles is likely to be related to measures of network centrality (Freeman, 1977), even though centrality remains an analytically and, to some extent, empirically distinct concept. Centrality reflects, in essence, the number of communication paths which pass through an individual's network location. That an individual is central, however, does not mean that he or she is integrated into a group, and vice versa. For example, simply receiving nominations, a crude index of centrality, does not guarantee one's membership in cliques and circles since these are based on dense interconnections within sets of individuals. An individual nominated by 20 persons all of whom are otherwise unconnected would not be a clique or circle member, although such nominations might reflect influence of another kind. On the other hand, because choices are assumed to be reciprocal, a reasonable assumption when the link is communication, it is possible for a sample member to be a member of a group even though receiving no interaction nominations, as long as she or he names two other persons at least one of whom names the other. What distinguishes persons outside of a group from those inside it is the absence of links joining the outsider to insiders who are directly linked themselves. Cohesion, then, is not simply equatable with greater density of links among circle or clique members, but rather with the integration of each member into tightly knit groups with other members.

It is important to indicate how the method used here compares with other methods which might be employed to study elite networks. What must be highlighted in considering its appropriateness is the precise correspondence between its basic mathematical concept, the maximal complete subgraph, and conceptions of

⁵ That is, although there are obviously not direct connections between all 876, it is possible for any one of them to reach any other through one or more intermediaries.

⁶ Some of the original three-person cliques had insufficient overlap with other cliques (i.e., they shared two or more members with none of the other groups) to be merged at any stage of the procedure.

group structure relevant to the study of integration. This correspondence gives the method used here considerable superiority over other methods that fall in the general class of clustering techniques (Bailey, 1975). Although these techniques may be quite useful in gaining some view of network data, and have been used widely for that purpose, in general they are heuristic strategies with no formal relation to network or group concepts.

Novel methods of network analysis have received considerable attention in recent years (e.g., Laumann and Pappi, 1973; White et al., 1976; Burt, 1976; 1978), but in general these methods are also less appropriate for the study of network integration than is the method used here. In essence, the method by which circles are identified is based on their internal structure and guarantees that a circle's structure is cohesive. The internal structure of groups or collectivities is less critical to other methods.

Blockmodeling, which has been used to study elite networks (Breiger, 1979), identifies blocks in terms of similarities in patterns of relations or "structural equivalence." Thus, the members of a block have similar relations to others both inside and outside of the block and need not be directly or indirectly tied to each other. Even when relations of a particular type are dense within a block, its internal structure, as defined by the direct and in-

direct linkages among its members, is not well-known without further analysis. In addition, the most common methods for constructing blocks (White et al., 1976) produce blocks which are mutually exclusive and hence one important mechanism for integrating groups—overlap of their memberships—is not considered.

The methods which Laumann and his colleagues (Laumann and Pappi, 1973; 1976; Laumann et al., 1977) have used to analyze elite influence structures are based on notions of social distance. While such notions are not incompatible with the method used here, maps of social distances do not in themselves indicate regions of cohesion, and, by construction, they take the existence of a "center" for granted. The method used here to identify social circles not only identifies collectivities with an important type of internal structure, but also leaves open the possibility that they do not exist, and thus that a network is fragmented.

FINDINGS: NETWORK STRUCTURE

As stated earlier, the procedure for identifying groups located 32 circles and cliques in the connected network from the American Leadership data. This connected part contains 876 persons and the remaining 65 individuals are all isolates, connected neither to each other nor to anyone in the network. Table 2 presents

Table 2. Network Position by Sector Membership

* Because all isolates are sample members, these percentages are the proportion of isolates in a given sample sector; other percentages in this table are based on the network of 876.

the network locations of individuals—whether they are isolates or, if in the connected network, whether they belong to a circle or clique—by their sector memberships.

As the table shows, just over half of the 876 persons in the connected network hold positions in the three federal political sectors, while the remainder represent a wide variety of nongovernmental institutions. However, in most sectors about a third of those in the network are members of circles or cliques. If only those in the original positional sectors are considered, this proportion is much higher only among political appointees and members of the media sector. The isolates—those sample members connected to no one else—come mainly from two sectors, political party and business. In the case of the political party sector, the isolates are local leaders,

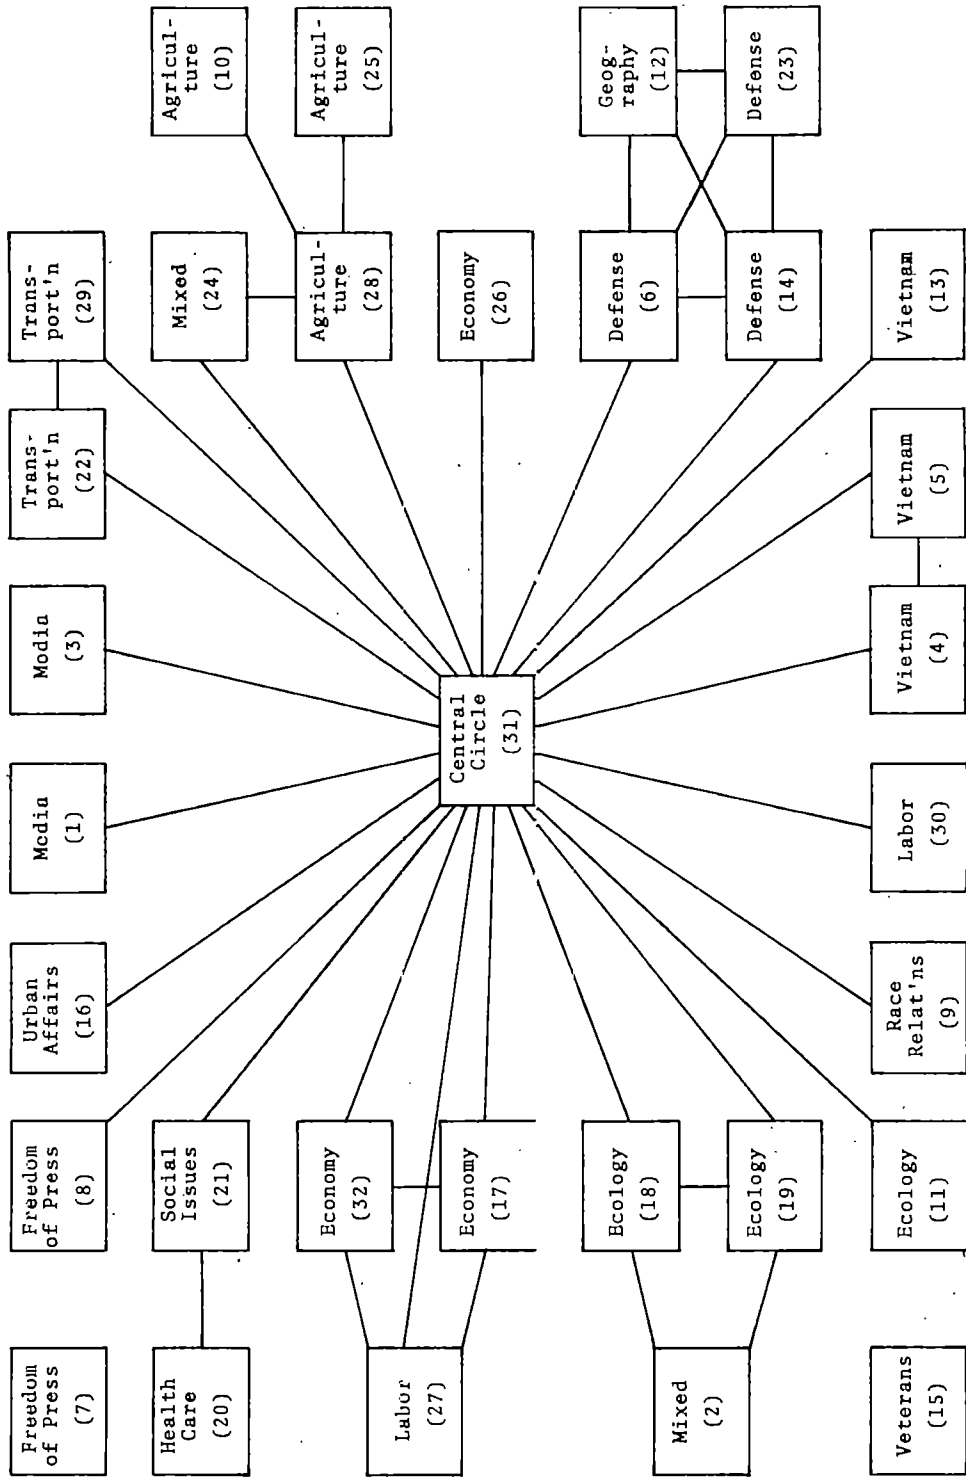

who have few, if any, ties to national elite groups. The isolated position of these local leaders is not surprising given the frequent description of American political parties as primarily local rather than national organizations. Most of the isolated business leaders are from the smaller organizations among the Fortune 800 corporations. For example, none is the head of an industrial corporation in the top 100 on the Fortune list and none is from one of the 20 largest insurance companies.

Of the 32 circles and cliques identified in the network, all but four are unified around concern with a common issue or through common sector membership, as Table 3 shows. Most of the groups are quite small. Only three have more than ten members and two of these are narrowly focused on one issue area each, ecology and agriculture. The third and most dis-

* Density is given as percentage of possible ties which are present.

* Numbers in parentheses in boxes refer to group numbers listed in Table 3.

Figure 1. Overlap in Membership of Elite Cliques and Circles*

tinctive circle contains 227 persons (of whom 164 are sample members) from all sectors and discussing all issues. It is the only one whose membership is large and inclusive, crossing sector and issue area boundaries.

Thus, with one prominent exception these are narrow groups of persons with similar issue concerns. Some are further specified by ideology. For example, three of the circles concerned with defense policy consist almost entirely of well-known conservatives in and outside the government, while two other defense policy groups have only members liberal on foreign policy.

The largest group of 227 persons is quite unlike the others because its membership is so diverse; it is in no way devoted to a single issue, sector or geographic region.⁷ This circle is broad and inclusive rather than narrow and specialized. Nearly one-third (30.1%) of all persons in the sample are members of this group. While this circle's density appears low when first compared with the densities of other groups (Table 3), its membership is in fact well connected, since its members have an average of 8.7 ties with each other. Also, it is composed of nearly 350 of the original, highly overlapping cliques and over half of its members belong to at least three of the cliques which have been aggregated to form it, while nearly 70% belong to at least two of these cliques.

This circle has many bridges connecting it to the more narrowly specialized, outlying circles and cliques, as Figure 1 clearly shows. The lines in this diagram indicate overlapping membership in each pair of groups connected by a line. Although not shown here, the proportion of overlap, i.e., the proportion of all members of the smaller group who are also members of the larger one, varies from a low of 16.5% to a high of 60.0%.⁸ Most of

the smaller groups have one, or occasionally more than one, member in common with the largest circle, although most members of the small groups are connected to the largest circle indirectly (through an intermediary), if at all. The small groups rarely have common members with each other. In the few cases where smaller groups overlap, the issue area involvement of members of each is generally similar, as in the case of three groups concerned with agricultural issues.

Ease of communication, then, is particularly true of the largest circle, within which dense connections among individuals from all sectors and issue areas exist. This circle's overlap with most other circles and cliques also allows members of the issue-specific groups to communicate directly or through an intermediary with the diverse membership of that large, generalized circle. Thus, in light of its size, inclusiveness and relations with the rest of the network, I call it the "central circle." The existence of the central circle and its connections to issue-based groups indicate that political elites in the United States are integrated not fragmented.

Although the central circle draws its members from all institutional sectors in the sample, representation of the various sectors is not equal, as Table 4 shows. As in the total network, just over half of the central circle members are from the federal political sectors. Aside from business, which has the largest nongovernmental representation, each other sector contributes less than 10% of the members of this circle. A rough assessment of the degree of over- and underrepresentation of sectors in the circle can be made in the following way: if each person in the sample had an equal chance of being a member of the central circle,⁹ each sector's proportion in the sample and the circle would be equal and the ratio of these proportions would equal one. When these proportions and ratios are compared it is obvious that this equal probability model is inaccurate.

Two of the three federal political sec-

⁷ However, the central circle probably contains regions or areas reflecting mutual interests or affiliations since many of the cliques combined to form this circle appear to have bases in such propinquities. This possibility is not pursued here since it is not germane to the issue of overall group integration.

⁸ Groups with overlap greater than 66.7%, it should be recalled, were merged during the computer analysis.

⁹ Sample proportions rather than those of the network are used in this comparison because nonsample network members had no opportunity to name interaction partners and thus their likelihood of being in the central circle is less than that of a respondent.

Table 4. Sector Composition of Central Circle and Sample

Sector	Circle		Sample Members in Circle		Sample		Ratio of Circle Membership to Sample Membership

tors are overrepresented in this circle, partly because specific sociometric questions were asked about contacts with persons in the federal government.¹⁰ In spite of these questions, civil servants are underrepresented in this circle, an indication perhaps that they are rarely included in high-level, broad-based elite circles. Members of the two snowball sectors—academics and state, local government—also are overrepresented in the central circle because in these sectors only persons nominated as influential were interviewed.¹¹

While persons in every sector had some chance of being in the central circle, members of the two high-level federal

political sectors and persons in the snowball sectors are considerably more strongly represented in the circle than in the sample. Nevertheless, the central circle is a group with broad membership, representing major public and private institutions and organizations. In addition, this circle is representative of the entire sample in terms of political party affiliation, age, sex and education. Democrats and Republicans had an equal chance of membership; nearly three-fourths of the circle and sample members are over 50 years old; 90% attended college; and virtually all (about 95%) of both groups are males.

*Attributes of Central Circle Members and Nonmembers*¹²

If the network analytic procedure has successfully located a circle of influential

¹⁰ Ideally responses to these questions would be excluded. However, since they are among the first sociometric questions in the interview and respondents rarely repeated names on subsequent questions, the exclusion of these questions would lead to an equally undesirable underrepresentation of important persons in the federal political sectors in the sociometric analyses. Nevertheless, the predominance of members of Congress and political appointees is not entirely a result of these sociometric questions. Although the exact effect on the network structure of the exclusion of responses to these questions is unknown, even when these responses are removed, members of these two sectors continue to receive disproportionately more interaction nominations than persons in other sectors.

¹¹ When these ratios are computed for members of the positional sample only (i.e., excluding respondents in the snowball sample), the results are roughly the same: members of Congress and political appointees are the most overrepresented and political party officials the most underrepresented in the central circle.

¹² Specific attributes beyond formal position of network and circle members are known only for persons in the sample. The remainder of the paper is then based only on respondents. The analyses which follow are based on the entire sample, both positional and snowball. Snowball sample members were retained for two reasons. One is to retain as many individuals as possible in analyses which must be done separately within each sector. The other is to retain in the analysis individuals who may have important characteristics, since they have been identified by others as "opinion leaders." However, it can be argued that the positional sample alone has a clearer relation to a population (Erickson, 1979:281). Therefore, the following analyses were also carried out for the positional sample only, with results very similar to those reported here.

elites, this should be independently verifiable by its relationship to other measures of influence. Even though virtually all persons in this study are occupants of elite positions, those who are central circle members can be expected to be more influential than other persons in similar positions. A central elite circle can be expected to contain among its members those individuals in high-level positions who are most active in policy influence activities, visible beyond their primary organization and influential among other elites. As indicators of policy influence activities I use three items: number of federal advisory committee memberships, number of times an individual has testified before Congressional committees,¹³ number of memberships in major policy planning organizations such as Council on Foreign Relations, Committee for Economic Development, Business Council.¹⁴ Visibility is measured by level of communications output, an index¹⁵ which includes recent interviews by the press, number of magazine articles and books written, and presentation of lectures. The number of reputation nominations received from other sample members is used as an indicator of influence among other leaders.¹⁶ Because activities, influence and visibility vary considerably from one sector to another, comparisons on these items are made within a given sector. Thus comparisons of characteristics of those who are and are not members of the central circle are always made among individuals in similar elite positions.

Table 5 shows that this central circle generally does contain the more influential persons in each sector. The three policy

influence measures included here clearly distinguish between circle members and nonmembers among persons in the private sectors. With the exception of the media, a sector whose members see themselves as reporters rather than influencers of events, circle members are more active than their noncircle colleagues in serving on federal advisory committees, testifying before congressional committees, and serving as members of important policy planning organizations. Circle members and nonmembers in the three federal political sectors are not distinguished by these measures, probably because policy influence activities are part of the job of all persons in such positions. Wide visibility, as measured by level of communications output, is far higher for members than nonmembers of the central circle in nearly all sectors. This potential influence over public opinion strongly distinguishes circle members from nonmembers. With the single exception of the media, whose role in influence differs from that of others in the sample, reputation for influence is much greater among persons who are members of the central circle than among their noncircle colleagues. Overall, the most striking differences are found for business elites, with central circle members scoring significantly higher than others in this sector on all of these indicators of influence. More generally, in most sectors this central circle includes in its membership the more active, visible and influential persons in elite positions.

The final question is: Do members of this circle have higher status origins and current affiliations than their nonmember colleagues in similar elite positions? Stated differently, do high status origins or current affiliations remain an advantage even after the achievement of an elite position?

Studies of recruitment into elite positions in major public and private institutions generally find that high status or upper class origins are an advantage in the achievement of such positions (for example, Keler, 1963; Prewitt and Stone, 1973; Parry, 1969; Mintz, 1975; Dye, 1976). These origins might remain advantageous even after achievement of such a position. Upper class members of the elite often are

¹³ Number of congressional testimonies is coded as 0 = 0, 1 = 1, 2 = 2 or more.

¹⁴ Also included are the following organizations: National Association of Manufacturers, Chamber of Commerce (national and international only), National Alliance of Businessmen, Foreign Policy Association, Rockefeller Foundation, Ford Foundation, Sloan Foundation, Carnegie Corporation, Hudson Institute, Rand Corporation, Russell Sage Foundation, Brookings Institution, Conference Board, American Assembly.

¹⁵ This index is standardized with a range of 0-1.

¹⁶ Nominations on interaction questions, the bases of the network analysis, are excluded here. The number of reputation nominations received ranges from 0 to 49.

Note: see text for variable descriptions; the academic and state, local government sectors are excluded because their numbers are too small for analysis.

seen as maintaining a nationwide network of informal connections throughout their lives which is generally not shared by others, including membership in exclusive private clubs, vacations at specific resorts and intermarriage (Mills, 1956; Domhoff, 1967; 1970; Baltzell, 1958; 1964). These ties are helpful in connecting one to a broad-based, nationwide network beyond that resulting simply from similar occupational or geographic locations.¹⁷ By contrast, individuals in elite positions without such connections are likely to achieve influence less as part of a broad-based network than through expertise in their occupational role.¹⁸

¹⁷ For the purposes of this paper I find the broader notion of social origins more useful than that of social class. Most occupants of top positions in major American institutions are not from upper class origins, however defined. There is a considerable range of origins, though skewed toward the upper end, among those in high-level positions. The expectation here is that the higher the status of an elite individual's origins the more likely he or she is to be part of a broad, informal elite network.

¹⁸ Compare this with Merton's (1957:414) discus-

sion of influence in Rovere, in which he suggests that monomorphic (issue or sphere specific) influence and polymorphic (in a variety of issue areas or spheres) influence have difference bases:

... the influence of the locals based largely on their personal "connections," ramifies into many and diverse spheres; influence of the cosmopolitan, more often stemming from certain types of expertness, tends to be more narrowly circumscribed.

¹⁹ Parents' socioeconomic status is composed of a four-point index of father's occupation, a five-point index of father's education and the same five-point index of mother's education; ethnoreligious origins is composed of a six-point index of generations of residence in the U.S., a three-point index of status of religion raised in, and a three-point index of status of ethnic origins; a three-point index measures high school type: elite private, other private, public or parochial; college quality is measured by a five-point index with no college lowest and Ivy League and Seven Sisters highest. All are standardized, with a range of 0-1.

cited as important in later achievement (e.g., Keller, 1963; Prewitt and Stone, 1973). As Table 6 shows, social origins differ little among members and nonmembers of the central circle in any individual sector. This is not due to little variation in social origins within each sector; each contains persons from a wide variety of backgrounds. For instance, while one in five of the business leaders' fathers never attended high school, a third graduated from college. Also, although a third of the labor leaders have fathers born outside of the U.S., the same proportion are from families which have lived in this country for at least three generations. Although in the majority of cases, circle members in a given sector have slightly higher social origins, the differences are generally small and rarely statistically significant. Parents' socioeconomic status is most frequently higher for circle members than nonmembers, but even here, differences

are rarely statistically significant. Only in the labor sector are two of these differences (parents' socioeconomic status and ethnoreligious origins) statistically significant. This suggests the possibility that labor leaders, who tend to come from far lower status origins than other elites, become members of a broad, elite circle only if they share at least some of the social origin characteristics commonly found in other elite groups. Overall, however, social origins play a minor role, at most, in distinguishing members of the central circle from others in similar elite positions.²⁰

Affiliations with prestigious organizations in the private sector might be associated with central circle membership even if social origins are not. For example, membership in exclusive social clubs or sitting on numerous corporate or non-profit boards of directors might be more common among central circle members than among others in similar formal positions.

Prominent social clubs are cited by Baltzell (1958; 1964) and Domhoff (1967; 1974; 1975) as important loci of interaction among members of the upper class, especially businessmen, in large cities. According to Domhoff (1967:19), their functions are:

... to provide an informal atmosphere in which new members of the upper class can be initiated into the mores that govern gentlemanly behavior. They also provide a place in which the groundwork for major business deals can be laid, and a place in which economic and political differences can be smoothed over in a friendly manner.

In addition, Bonacich and Domhoff (1977) find considerable overlap in the membership of exclusive social clubs, major business corporations and influential policy planning groups such as the Committee for Economic Development and the Council on Foreign Relations. They contend that this overlap indicates the existence of a nationwide upper class which is

²⁰ Of course this does not mean that occupants of elite positions come from social origins similar to those of members of the U.S. population as a whole. Rather, it implies that high status origins are of no additional advantage once an elite position has been achieved.

significantly represented in not only major economic institutions but also policy groups which have important inputs to government decision making. Given the importance of upper class clubs, one would expect their members to be more likely than others in similar positions to be included in a central elite circle.

Elite individuals with broad connections and prestigious affiliations beyond their primary institutions would also appear more likely than others in elite positions to be part of a central circle. Useem (1978:226) argues that the inner group of the capitalist class consists of individuals with the broadest spans of control over major business firms. A broad span of control is achieved by persons who are executives of major corporations and also sit on several boards of directors of important firms. Similarly, though not confined to the economic sector, Perrucci and Pilisuk (1970) contend that interorganizational ties lead to broad resource networks which are less readily available to persons with prominent positions in a single organization. In a study of interorganizational ties in a midwestern community they found that persons holding executive positions in many organizations, as compared with those holding a single such position, were more involved in community issues, enjoyed greater reputations for power and tended to see one another socially (Perrucci and Pilisuk, 1970:1056). In light of these findings, it is easily argued that membership on many corporate boards or even nonprofit boards might lead to participation in a national elite circle. Persons who serve on several corporate or nonprofit boards would be more likely to be members of a central circle than their colleagues who serve on fewer or no boards of directors and who thus have narrower resource networks and/or spans of control.

Table 7 shows that central circle members are not more active in these organizations²¹ than their noncircle col-

leagues. While persons in the central circle are generally members of more nonprofit boards of trustees than similar non-circle members, these differences are not statistically significant. Social club membership does, however, distinguish circle members from others in some sectors. Only among business and media leaders is membership in a social club common, and in both of these sectors central circle members are about twice as likely to belong to an exclusive private club as their fellow sector members who are not part of this circle. In fact, three out of five business leaders in the central circle are members of a social club, by far the highest proportion of any group. Most individuals

²¹ Social club membership is coded one if respondent belongs to any upper class clubs (as listed by Domhoff, 1970:23-6) and zero if he or she is not a member of any of these clubs. The variable for corporate boards of directors reflects the number of corporate boards on which respondent has ever

served. Nonprofit boards of directors or trustees is the number of college, foundation or similar nonprofit boards of directors or trustees on which respondent has ever served.

in this sample are members of more than one board of directors and trustees, with the highest average in the business sector; nevertheless, the number of board memberships in a given sector differs little between those who are and are not members of the central circle.

Briefly, high status social origins are at most a very small advantage to those in elite positions in becoming connected to a central leadership circle. Similarly, affiliations with elite private sector organizations are generally unrelated to central circle membership. However, it should be noted that Domhoff and Baltzell are right in contending that social club membership is important for business leaders.

CONCLUSIONS

The purpose of this paper has been to examine the structure of an elite network in major American institutions as a way of assessing the extent of integration among political elites in the United States. No fragmentation of elites in different institutions or issue areas was found. On the contrary, the evidence examined here indicates that considerable integration exists among elites in all major sectors of American society. The existence of a central elite circle facilitates communication and interaction both within that large, diverse group and between its members and those in more specialized elite circles and cliques.

In a critique of elite theories, Dahl (1958) argues that elite theorists often make the error of equating a high potential for control with actual power. He contends that the formation of a ruling elite requires not only control of important resources, but also the achievement of unity and cohesiveness among its members (see Wrong, 1968, for a related argument). The structure of this network and especially the central circle indicate at least a potential for unity among these elite individuals, almost all of whom have a high potential for control through their incumbency in high-level positions. Thus the structure exists through which elites in various institutions in the U.S. could become unified in the pursuit of common goals.

Yet, in another way, the structure of the elite network analyzed here does not support a critical aspect of the contention that American elites form a cohesive ruling group acting in concert to further common interests. Implicit or explicit in much work on the structure of power in the United States (e.g., Mills, 1956; Domhoff, 1967; 1970) is the assumption that the solidarity of its ruling elite is founded in part on the upper class origins of many of its members, together with the common experiences and mutual connections such origins foster. Linked to this assumption is another: that upper class origins and their associated connections confer important advantages on the individuals possessing them in moving into the highest circles of power and influence. But the integrated network found in this study is not based on similarities in the social origins and affiliations of its members, to say nothing of upper class origins. While central circle members are more influential than others in similar formal positions, they differ little from the latter in social origins or connections to major private sector organizations. The very diversity of the central elite circle is inconsistent with the expectation that upper class origins and connections are frequently decisive in attaining significant national influence, as it is with the expectation that the solidarity of the highest circles is founded in part on shared origins and mutual upper class affiliations.

This apparent impotence of upper class origins should not be misunderstood. The role of social origins in the attainment of a position in the political elite has been well documented (Domhoff, 1967; 1970; Dye, 1976; Keller, 1963; Mintz, 1975; Prewitt and Stone, 1973). It is at the stage of attainment of an elite position that social origins serve to exclude most Americans from the opportunity to influence national policy making in significant ways. However, once such a position has been achieved, as is true of virtually all persons in this study, these factors are of little subsequent importance. While the importance attributed to social origins in the formation of elite groups is only one part of the ruling class view of American society, the findings of this study appear to

indicate the need for serious revision of this view.

Even so, it is necessary to underline that these data are limited, as are any data. Thus, they cannot disconfirm one version of ruling class theory which discounts completely the importance of social origins among members of the political elite in a society with a capitalist economy. This version, in effect, argues that bias in favor of capitalist interests is built into the American system of policy making, guaranteeing that those interests are protected by occupants of important positions, whatever their origins (e.g., Poulantzas, 1973; Miliband, 1969; Schattschneider, 1960). Data about social networks do not seem generally suited to a consideration of this possibility. In addition, one could argue that social origins and connections play a crucial role in the workings of elite circles during times of crisis or when issues of "life and death" significance for powerful groups in American society, such as its capitalist class, are under consideration.

Perhaps the most reasonable interpretation of the network analyzed here is to see it as one involving day-to-day discussions of major issues that have appeared within the public arena. In this light, the structure of the central circle—broad and inclusive, rather than narrow and exclusive—suggests that one of its main functions is the negotiation of conflict among major organized groups in American society. Crucial then are the ways in which the central circle directly and indirectly integrates leaders of a wide variety of institutions into a network capable of discussing and resolving issues of national concern.

THE OPEN AND CLOSED QUESTION*

HOWARD SCHUMAN
University of Michigan

STANLEY PRESSER
University of North Carolina

American Sociological Review 1979, Vol. 44 (October):692-712

Two quite different reasons for employing open as opposed to closed attitude questions can be distinguished. One is to discover the responses that individuals give spontaneously; the other is to avoid the bias that may result from suggesting responses to individuals. The first goal can be satisfied through careful pretesting, whereas the second requires that open questions be used in the final questionnaire. We examine both goals by means of experiments within large-scale sample surveys. A widely used closed question on Work Values is first compared with a parallel open question, and then the responses to the latter are used to reformulate the closed alternatives in new comparisons. More limited experiments on two other items also are discussed. In all cases there are large and reliable differences between question forms in univariate distributions, and in most cases important differences in bivariate relations also occur. An attempt is made to explain and reconcile both kinds of differences. The evidence suggests that if closed alternatives initially are constructed on the basis of sufficient open responses, then remaining open/closed differences may be due mainly to interviewing and coding problems with open questions, rather than to bias from closed questions.

"Since the beginning of social research," wrote Paul Lazarsfeld (1944), "students have tried to combine the value of detailed qualitative applications with the advantages of more formalized techniques which could be managed on a mass basis." Since Lazarsfeld's often cited

paper was written, the controversy over open as opposed to closed modes of inquiry in surveys has been largely resolved in practice by the victory of the closed form—no doubt because of the evident efficiency of such questions for interviewing, coding, and analysis. Despite a few exceptions, the results of social surveys today are results based mainly on what are varyingly called closed, fixed-choice, or precoded questions.¹

What is most remarkable about the triumph of closed questions is that it oc-

* Direct all communications to: Howard Schuman; Institute for Social Research; University of Michigan; Ann Arbor, MI 48106.

We are grateful to Jean M. Converse and Jacob Ludwig III for advice and help at numerous points, and to James House, Richard Kulka, Gerhard Lenski, and Charlotte Steeh for their suggestions. This paper is based upon work supported by the National Science Foundation under Grant No. Soc. 76-15040.

¹ The General Social Survey of the National Opinion Research Center (NORC) deliberately excludes open attitude questions entirely.

curred with so little direct confrontation of the two question forms. Despite the controversies among practitioners and organizations in the thirties and forties, and the endless discussions in textbooks ever after, it is difficult to locate a single rigorous experiment in which closed and open versions of essentially the same attitude question were asked of the same general population in a split-ballot or other experimental design. Argument for the superiority of one form or the other is based almost entirely on common sense and anecdotal experience.² The present report, limited though it is, seems to be one of the few systematic attempts to compare complex open and closed questions within the framework of the standard large-scale attitude survey.

PRESUMED ADVANTAGES OF OPEN QUESTIONS

When all is said and done, there appear to be two principal arguments for using open questions in attitude surveys despite their greater inefficiency. First, closed questions constructed in an *a priori* way may fail to provide an appropriate set of alternatives meaningful in substance or wording to respondents. This argument, however, leads straight to the recommendation of Lazarsfeld (1944) and others (e.g., McKennell, 1974; Moser and Kalton, 1971) that survey questionnaire design should *begin* with open questions in pilot or pretest work, then use the resulting responses as a basis for developing a meaningful set of final closed alternatives. Such sensible-sounding advice is perhaps more often preached than practiced—and

² A recent treatment by Bailey (1978:104–8) is fairly typical. It discusses in a sensible way a large number of advantages and disadvantages of one form as against the other, but cites no empirical evidence. The issue apparently is regarded as settled, since the Instructor's Manual (Kiecolt, 1978) for the book offers the following multiple-choice item for testing students, with the first alternative keyed as "correct":

Which of the following is the best type of question for gathering information about complex issues?
(a) open-ended, (b) closed-ended, (c) interval-level"

In our concluding remarks we will discuss the few empirical open/closed comparisons that we have located in the survey literature.

even where practiced is usually compromised by the small, unrepresentative, and hurried nature of much pretesting. In any case, it indicates a preliminary rather than a definitive advantage of open questions.

The second argument is that respondents are apt to be influenced by the specific closed alternatives given, and that therefore a more valid picture of respondent choice is obtained if they must produce an answer themselves. There are several versions of this argument; for example, an interest in measuring what is most "salient" to respondents, a desire to avoid "social desirability" effects, a concern to prevent mechanical choice or mere guessing. All these have in common the assumption that the superiority of open questions is inherent in the form, and cannot be provided through *any* precoded set of alternatives.

PRESENT AIMS AND DATA

Ideally, experiments comparing open and closed questions should test separately *both* advantages of open questions. We succeeded in doing this fully in only one instance, but made two other attempts where the failures are also instructive. As in our other experiments on question form (Schuman and Presser, 1977), we attempted to start from items of some demonstrated usefulness—a question on Work Values, one on Child Values, and one on the Most Important Problem facing the United States—each of which had appeared in one form or the other in an important past survey. The Work Values experiments were carried furthest, and we therefore concentrate on them here, and draw on the other two items more briefly toward the end of the paper.

Two possible kinds of open/closed differences are of interest: (1) differences in "marginal" or univariate distributions that purport to say something about the importance of one value or problem compared with another, and (2) differences in bivariate or multivariate relations, which the analyst uses in trying to discover the location and determinants of responses in a general population. Our results will be relatively straightforward where open and

closed forms do *not* differ beyond sampling error in either of these two ways. In such cases, survey investigators are free to use whichever form suits them, though cost considerations will undoubtedly push toward closed questions. The matter is more complex where differences do occur, since the issue of which form is more valid naturally arises at that point. We will not be able to provide definitive evidence on this issue, but the problem will be posed sharply and some conclusions offered.

Our data come from five cross-section surveys in which different forms of a question were administered to random halves of the same sample. The first survey, carried out in 1976 by the Detroit Area Study (DAS-76), involved face-to-face interviews with a cross-section of 896 adults in metropolitan Detroit. The other four surveys were administered by the University of Michigan's Survey Research Center (SRC), using telephone interviewing, to cross-section samples of the national population in February 1977 (N=1,203), August 1977 (N=1,218), August 1978 (N=1,144), and January 1979 (N=884). (We refer to them below by organization, year, and month, e.g., SRC-77February.) Five experiments were carried out on the Work Values item, one in each of the surveys just described. Experiments with an item about the nation's Most Important Problem appeared in DAS-76 and SRC-77February, and one dealing with a question on Child Values in DAS-76.³

³ For a full description of the DAS-76 sample, see Bianchi, 1976. The SRC samples were selected by random digit dialing, with part of the respondents chosen fresh and part recontacted from previous surveys—a design developed for use in analyzing questions on consumer behavior that make up most of the questionnaires. Since all the recontacts in SRC-77August originally had been interviewed in SRC-77February, we are able to merge their responses from the two surveys and treat these as panel data in certain analyses described below. It also seemed possible that recontacts might answer questions differently a second time than new respondents, hence we examined this in SRC-77August by comparing both marginals and relationships involving the two Work Values forms for the two subsamples: no differences approaching significance have been discovered. In other parts of our larger project we also have attempted to determine whether varia-

THE WORK VALUES EXPERIMENT

Experiment 1: DAS-76

In a study of *The Religious Factor* in American life, Lenski (1963) employed the following closed question about what people value in jobs, asking it of a sample of metropolitan Detroit:

This next question is on the subject of work. Would you please look at this card and tell me which thing in this list you would *most* prefer in a job? (MARRIED WOMEN: . . . in your husband's job?) Which comes next? (ETC. TO OBTAIN RANKING)

1. High income;
2. No danger of being fired;
3. Working hours are short, lots of free time;
4. Chances for advancement;
5. The work is important, and gives a feeling of accomplishment.

In later years this question occasionally was repeated by the Detroit Area Study (see Duncan et al., 1973), and in 1973 it was adapted by NORC for inclusion as a standard item in its General Social Survey (NORC, 1977). The NORC version differs only in that it asks all respondents about their own preferences rather than asking wives about their husbands' jobs.

We first employed the NORC version of the Work Values item with a random half of the DAS-76 sample; we administered at the same time an open version of the question to the other half of the sample.⁴

tions either in response rate or in telephone vs. face-to-face interviewing mode affected our results. Very few such effects have been found, and none relevant to the present report. It also should be noted that although our sampling involved a small amount of clustering, the design effects for most attitudes are very small (usually 1.1 or less) and we have used SRS calculations of statistics, relying on replication to assure the reliability of borderline results. All X^2 statistics are likelihood-ratio calculations, and our analyses of multiway contingency tables are based on Goodman (1971).

⁴ The closed version of the Work Values question asked for a second choice as well, but we do not deal with those results here since the open form had no similar follow-up question. Respondents did sometimes give two or more codable responses to the open form, but in these cases interviewers were instructed to ask which one represented their main preference. Occasionally this probe was omitted and such responses here are treated as missing data (code 96). An alternative and more common procedure would be to automatically code the first mentioned response. For the third item discussed below

Table 1 presents both forms of the question, the codes for the open form, and the univariate results from this first experiment.⁵ The first five categories are meant to be comparable across closed and open question forms, although in this first experiment we did not maintain exact identity in labels and there are some substantive differences to be discussed below. Additional new substantive categories were created (on the basis of preliminary review of 150 cases) to handle open responses that did not fit well the main five categories, and these will also be discussed below.

Univariate results by form. Several conclusions can be drawn from Table 1.

1. All but a tiny fraction of the closed responses fall within the five precoded categories, but nearly 60% of the open responses fall *outside* these same five categories. Thus the two questions show gross differences in the answers they elicit. Respondents on the closed form restrict themselves with apparent ease to the five alternatives offered, while respondents on the open question produce a much more diversified set of answers.

2. If we confine our attention to the five categories common to both question forms, it will be noted that the first two categories produce almost identical percentages, the third only a little discrepancy, but the fourth (Advancement) and fifth (Accomplishment) lead to major differences. (The overall difference in univariate distributions by form for the five-by-two table is highly significant: $X^2 = 46.8$, $df = 4$, $p < .001$.) Evidently, the Advancement and Accomplishment alternatives are much less often stated spontaneously than they are chosen when offered explicitly.

(Child Values), we examined those multiple response answers that had been probed in order to determine whether there is indeed a relation between the order in which responses are given and their importance as judged by respondents. Of 55 persons giving two codable Child Value responses, the probe for "most important" led 27 to pick their first and 28 their second response. Thus, order seems unrelated to importance.

⁵ Check-coding of 72 of the open responses yielded perfect agreement in 76% of the cases. All later experiments reported in this paper had agreement percentages above this level, usually in the eighties.

3. It is necessary to keep in mind—and often easy to forget—that even for the five common categories, meanings may be different between the two forms. Thus, open category 2 on Security is probably broader in content than the comparable closed category (No danger of being fired) and therefore even the apparent similarity in percentages may be misleading. One recurrent problem with open categories is that their labels and examples may not tell us enough about what actually has been coded into them. Of course, the same is true in another sense with regard to closed alternatives, since an alternative may carry different meanings to different individuals. Reification of categories is a serious hazard in both forms.

4. What of the categories that appear on the open form but not on the closed form? Two new types of responses occurred with enough frequency to justify new substantive codes. Fifteen percent of the open sample responded in terms of the job being pleasant or providing enjoyable social relations. We grouped all these types of responses into a single category (6), which turns out to be one of the larger ones in the table. A different but almost equally common kind of response is grouped under Work Conditions (7), referring both to autonomy of the job and to more concrete job factors such as safety. Along with these clearly meaningful new responses is an increase on the open form in the "Don't know," "Other," and related kinds of missing data (categories 95–99). Perhaps better interviewing would reduce these categories, but we believe that open questions tend in general to produce more missing data. Finally, the category Satisfaction (8) seemed to us at first to contain essentially tautological responses and thus to be another form of missing data, but later analysis (reported below) suggests that it represents a meaningful if vague kind of answer.

Background variables and work values: sex and education. It has been a traditional, though usually implicit, assumption of survey analysis that the form differences we have been describing do not extend to associations between an item and other variables. In order to test this assumption of "form-resistant correla-

tions" (Schuman and Presser, 1977), we employed education and sex throughout our analysis because they are two of the most frequently used and important variables in survey research regardless of the content of the study. They also are not

redundant with each other (their association in DAS-76 is trivial and nonsignificant); they apply to all respondents (as occupation does not); and they have few missing data (unlike income). In addition, we began this research with a general hy-

Table 2. Work Values by Sex and Form: Experiment I

	Closed		Open	
	Men	Women	Men	Women
1. Pay	16.3%	9.5%	10.5%	12.2%
2. Security	8.2	6.4	10.5	3.7
3. Free Time	2.6	3.4	0.0	1.6
4. Advancement	21.9	13.6	2.1	1.6
5. Accomplishment	50.0	65.9	24.2	19.1
6. Pleasant			12.1	17.9
7. Work Conditions			13.2	16.3

pothesis that more educated respondents would be less affected by question form variations than the less educated, on the assumption that education is associated with somewhat more self-developed and stable concepts.

Sex does show a different relation to Work Values on the two forms, as indicated by a significant three-way interaction of form, sex, and response ($X^2 = 12.2$, $df = 4$, $p < .02$). (In this and later analyses, significance tests are calculated only for categories common to the two forms, but tables show all categories.) Based on the closed form one would conclude that men are more likely to value Pay and Advancement, while on the open

form there seems to be little sex difference in these respects (see Table 2). On the other hand, on the closed form women are more apt to stress Accomplishment, with if anything the reverse being the case on the open form. Furthermore, women are more likely to give codable open responses that fall outside the five categories common to the two forms, in particular responses coded Pleasant.

When education is the background variable rather than sex, the three-way interaction is of borderline significance ($X^2 = 13.9$, $df = 8$, $p < .10$). It is more difficult in this case to pinpoint differences (see Table 3) or to be certain of their reliability, but data to be presented from later ex-

periments suggest that the trends for the Security category to differ by form are meaningful.⁶

Conclusions from Experiment I. Our comparison of open and closed forms of the Work Values question indicates that marginals for the two differ in important ways, and that the nature of associations of background variables with Work Values also differ by form. Thus it seems unwise to draw conclusions about the character of American work values from the absolute size of closed categories, as Lenski did in his 1963 volume, or even from the relative ranking of choices, as Duncan et al. (1973) did in a later replication. Advancement, to take the most striking example, differs in both percentage and rank in the open as compared with the closed results. Moreover, it is unclear which form provides the more valid representation of respondent values: proponents of open questions can hold that a value is not really important if it is seldom offered spontaneously, while proponents of closed items can argue that that form provides a fairer test by presenting the same frame of reference to all respondents. Both positions seem plausible, and it is difficult on an a priori basis to decide between them.

However, while this form comparison throws some light on the Work Values alternatives as they have generally been asked, implications for the open/closed controversy are limited by the fundamental ambiguity discussed earlier. Discrepancies by form could have come about merely because the closed alternatives fail to capture what many people want to say in answer to the question, either because the five alternatives were not developed initially on the basis of open pretesting, or having been so devel-

oped in the 1950s may no longer represent well the responses of the present. Therefore, we decided to use the open data in Table 1 as a kind of large-scale pretest to construct a new set of closed categories reflecting more adequately how people spontaneously answer the Work Values question in the mid-seventies. We also took this opportunity to clarify or otherwise amend the phrasing of certain closed alternatives, as will be described below. In taking these steps we necessarily gave greater weight, at least for the moment, to categories constructed from the free answers of respondents than from categories created a priori by an investigator.

Work Values Experiments IIa and b

In the next experiment (SRC-77February) we attempted to create a new set of alternatives as representative as possible of the open responses just discussed. This experiment (IIa) produced results that seemed important to test further for reliability and validity, and hence IIb was carried out as an exact replication a year and a half later (SRC-78August). To conserve space, the two are combined here where possible in tabular presentation and discussion, but analysis was carried out for each separately and similarities and differences in results will also be noted.⁷ Both these new

⁶ We also examined Protestant-Catholic differences by form, since the closed Work Values item was used by Lenski to study such differences. In the DAS-76 sample there is a trend on the open form for Protestants to give what Lenski considered the primary Protestant Ethic response—Accomplishment—more often than Catholics, but not on the closed form. However, the interaction is not significant and the results for the closed form differ from those obtained in earlier studies and from a later partial replication (Experiment IIb).

⁷ The '77 February and '78 August samples differ somewhat in within-household selection. The former required random selection of any adult, but the latter required selection in three quarters of the cases of heads of household only. However, our analysis indicates that none of the results reported in this section are a function of this difference. Comparison of the two surveys within form does show a highly significant ($X^2 = 20.23$, $df = 4$, $p < .001$) change in Work Values marginals for the closed form between February 1977 and August 1978: virtually all of the change involves a sharp rise in the Pay choice, with compensating smaller declines in Accomplishment and Pleasantness. Since similar trends appear on the open form, but to a smaller and nonsignificant degree, it seems likely that the difference reflects real changes in value emphasis in the national population, perhaps due to the impact of inflation, rather than to coding or other survey-related problems. (The changes are not due to sampling differences, since they occur to the same extent when only male heads are considered.) Despite these univariate differences between Experiments IIa and IIb, all bivariate and trivariate results reported in this section hold within

experiments used national telephone samples, whereas our earlier data came from a Detroit SMSA sample and employed face-to-face interviewing. It was therefore necessary to assume that the earlier results could be used as a pretest for the later study. This assumption can be tested by comparing the open percentages from Table 1 with the new national open percentages in Table 4. Although there are some differences, they are not major and none would have led to changes in the decisions we reached on the basis of the earlier DAS results.

The following changes were made in the alternatives of the closed form for Experiments IIa and b. In certain corresponding instances, labels and definitions of open code categories also were altered, as noted.

First, two alternatives were *dropped* because they had shown tiny open percentages in Experiment I: Short Hours and Advancement (3 and 4 in Table 1).

Second, two closed alternatives that had elicited substantial percentages on the open form were *added*. Pleasantness and Work Conditions (codes 6 and 7 in Table 1). Both category labels were somewhat changed in the closed version, with corresponding changes in the open code labels (see codes 4 and 3 in Table 4). Pleasantness was simply spelled out more clearly to include both the sociability and the general enjoyment responses that had been coded on the DAS open form. Work Conditions, however, was changed to focus on autonomy ("Work where there is not too much supervision and you make most decisions yourself"), which had seemed to us the main content of the previous open code; a new corresponding open code on Autonomy was created. (The label Work Conditions, however, was retained as an open code for purely physical conditions of the environment, and should not be confused with the more omnibus label used in Table 1.)

Third, three alternatives retained from the 1976 Table 1 closed form were each relabeled in order to correspond more

closely and clearly to the content of the Table 1 open categories, specifically:

- (a) "Work that gives a feeling of accomplishment" is a shortening of the alternative, "The work is important and gives a feeling of accomplishment." The latter seemed at once redundant and loaded in a socially desirable fashion by stressing "importance." We expected this change to decrease the closed percentage, bringing it closer to the percentage that spontaneously gives the Accomplishment response to the open question.
- (b) "Work that is steady with little chance of being laid off" is an expansion of "No danger of being fired." The latter seemed to us unduly limited and not to capture the real concern over job security that appears important to respondents. (However, open responses dealing entirely with fringe benefits were separated out into a new Benefits category.) The reason for this change was entirely conceptual, since the change might be expected to increase rather than decrease the open/closed difference.
- (c) "Work that pays well" is the new name of what Lenski called High Income. The new label was intended to apply more easily to all job levels, though we expected at most a slight effect on responses.

Thus all five closed alternatives are either newly developed or reworded to fit our experience with open responses in the previous survey as closely as we could manage. (The five will be referred to below as: Pay, Accomplishment, Autonomy, Pleasantness, and Security.) Furthermore, in Experiments IIa and b we were careful to use essentially the same labels for the parallel closed alternatives and open categories, and open coders were trained to think in terms of these labels.

One further refinement was added in Experiment IIa in order to check for a possible order effect on responses to the closed form. The closed version of the question actually consisted of five ran-

the two surveys separately. Therefore subsequent tables present combined results only.

Table 4. Work Values: Experiments IIa and b Combined^a

Closed Question		Open Question	
This next question is on the subject of work. People look for different things in a job. Which one of the following five things would you <i>most</i> prefer in a job?		This next question is on the subject of work. People look for different things in a job. What would you <i>most</i> prefer in a job? (Consider codes 1-5 High Priority)	
1. <i>Work That Pays Well</i>	13.2%	1. <i>Pay</i> (work that pays well) Remuneration, e.g., "The money is what counts"; salary; wages; overtime; bonuses; profit sharing.	16.7%
2. <i>Work That Gives a Feeling of Accomplishment</i>	31.0	2. <i>A Feeling of Accomplishment</i> Work that makes some demand on the worker, e.g., "Work that is challenging," "work that leads to fulfillment," "crea- tive," "helping people."	14.5
3. <i>Work Where There Is Not Too Much Supervision and You Make Most Decisions Yourself</i>	11.7	3. <i>Control of Work</i> (work where there is not too much supervision and you make most decisions yourself) Factors affecting how job is done, e.g., "Being able to set one's own pace," "being free from interference."	4.6
4. <i>Work That Is Pleasant and Where the Other People Are Nice to Work with</i>	19.8	4. <i>Pleasant Work</i> (. . . and where the other people are nice to work with) Usually concerns pleasant social relations, e.g., "Congenial people." Code here un- specific mentions of "happiness" and mentions of the social situation at the workplace.	14.5
5. <i>Work That Is Steady with Little Chance of Being Laid Off</i>	20.3	5. <i>Security</i> (work that is steady with little chance of being laid off) Steady employment and source of income, e.g., "No chance of being fired."	7.6
		6. <i>Opportunity for Promotion</i> Chance for advancement, e.g., "The chance to get ahead."	1.0
		7. <i>Short Hours/Lots of Free Time</i> Jobs that give time for other things, e.g., "The chance to be with my family."	1.6
		8. <i>Working Conditions</i> "Good lighting," "well insulated," "safe."	3.1
		9. <i>Benefits</i> Health/life insurance, retirement plan.	2.3
		10. <i>Satisfaction/Liking the Job</i> Unspecific answers not codable in 02 or 04, e.g., "Doing what I like," "being satisfied with the job is most important."	15.6
		95. Code here mentions of specific jobs, e.g., "I'd like to be a teacher," that are not otherwise codable.	3.7
		96. More than one codable response with no indication of which is most important.	4.0

^a Carried out in SRC-77February and SRC-78August.

domly administered subforms—each of which began with a different alternative and continued sequentially through the other four. Thus, although not every possible permutation of the five alternatives was tried, each alternative appears first in one subsample, second in another, and so on. Cross-tabulation of the five orders by the five choices yields no sign of a primacy, recency, or other systematic type of order effect, and the overall table shows no relationship between order and response choice: $X^2 = 15.2$, $df = 16$, $p > .50$.

Form Differences in Marginals

Given a method of construction designed to maximize similar results from open and closed forms, how successful was the effort? The answer appears to be: Somewhat successful, but not by any means completely so. Examination of Table 4 yields the following results.

1. *Spread of responses.* Open responses still spread substantially beyond the five categories common to both forms, but these categories on the open form now contain 58% of all open responses as against 42% in the first experiment ($X^2 = 30.9$, $df = 1$, $p < .001$). All but one of the open common categories (and all of the closed alternatives) produce more than trivial percentages, and no other large open category (with the exception of the vague Satisfaction category) appears outside the common set of five.⁸ In sum, our five focal work values seem to have captured more adequately the spontaneous answers of respondents, though there are still a variety of small substantive and missing data categories.⁹

⁸ The one failure here is the Autonomy category, which draws only 4.6% on the open form. If the Working Conditions category is joined to it, the percentage rises to 7.7%. We were incorrect in believing that Autonomy alone would be an adequate size category.

⁹ In Experiments IIa and IIb (but not Experiment I) we instructed coders to give priority in ambiguous cases to the first five categories. However, a later recoding of 50 randomly drawn cases from Experiment IIa by a new coder not using the priority system produced only a single response where the priority instruction might have changed the assigned category, and even this one was equivocal.

2. *Effects of relabeling on closed alternatives.* Three alternatives were carried over from Experiment I, but relabeled, and two of these show marked shifts in size from the first experiment. Security goes *up* from 7% in the first experiment to 20% in the second, in line with its expansion in meaning from "No danger of being fired" to "Work that is steady with little chance of being laid off." At the same time, the Accomplishment category goes *down* from 59% in the first Experiment to 31% in the second, as might have been expected from omission of the loaded phrase, "The work is important." However, these percentage shifts could have been due to the change in the total set of alternatives offered respondents, rather than to rewording of individual alternatives. Since the possible effects of "social desirability" of wording on choice is an important issue in using closed questions, we tested the change in the Accomplishment alternative in a later experiment (SRC-79January). The closed Work Values question from Table 4 was asked to half this sample, while the other half received a question identical in all respects except that the phrase, "The work is important," was added back into the Accomplishment alternative. Contrary to prediction, this change did not produce a significant difference ($X^2 = 1.1$, $df = 1$). Thus we find no evidence, even in the case where we most expected it, for social desirability of wording to play a role in respondent choice of an alternative.

3. *Overall form differences.* If we confine our attention to the five categories in Table 4 that are common to both question forms, there is a noticeable difference for each category, with Pay yielding a higher percentage on the open form and the four others a higher percentage on the closed form. The latter might occur simply because open responses are spread over more categories, hence on each form we repercentaged the five common categories on their own base. However, the mean repercentaged form difference is only slightly smaller (7.8%) than the mean difference using the original percentages (9.0%), and the overall difference between forms is highly significant: $X^2 = 82.0$, $df = 4$, $p < .001$. Pay and Pleasantness are

given relatively more often on the open form, while Accomplishment, Autonomy, and Security are given more often when a precoded list is presented. Moreover, the rankings of the five values, which are unaffected by repercentaging, also differ between the two forms, as indicated most strikingly by the fact that Pay ranks first in frequency of response to the open question and close to last to the closed question.

Were it not for one important exception, a more general post factum interpretation of these findings would be persuasive: most respondents think in terms of material benefits, social pleasures, or absence of demands when required to provide their own work values, but are strongly attracted to "higher" aspects of work (especially the opportunity for a sense of accomplishment) when these are suggested to them. The latter would then be due more to a type of social desirability response than to genuine desire for more challenging work. However, the pattern for Security does not fit this interpretation, since security is hardly a challenging characteristic of a job, yet it shows one of the largest increases when we move from an open to a closed format. Evidently the process is not entirely—or possibly not at all—one involving social desirability of response, but has something to do with the frame of reference that a respondent brings to questions about work. The plausibility of this interpretation is increased when we consider the relation of open/closed form effects to background variables.

Relation of Form Differences to Education, Sex, and Unemployment Experience

Education. Although education is significantly related ($p < .001$) to Work Values on both open and closed forms, these relations (shown in Table 5) also differ significantly between the two forms ($X^2 = 27.5$, $df = 8$, $p < .001$). Most strikingly, the Security category on the closed form reveals a sharp negative association with education, while on the open form Security shows no clear relation to education. (The interaction of form, education

and Security vs. other common categories combined yields: $X^2 = 23.9$, $df = 2$, $p < .001$). This difference for the Security alternative is equally strong in Experiments IIa and IIb taken separately; it is even more striking when five educational levels are used instead of three; and the same trend appeared in Experiment I. Careful examination of Table 5 suggests a partial interpretation for the different relations of Security to education, an interpretation that takes account of the somewhat opposite trends for the Pay category (Pay shows a negative association with education on the open but not on the closed form). We believe that the *open* Pay category fails to distinguish two different types of responses: those referring to high income and those referring to steady income, and that this is especially true for less educated respondents who may simply verbalize something ambiguous such as "It's the money that counts." The closed form of the question allows these respondents to clarify their views, since it makes the Pay/Security distinction explicit. We thus learn from the closed form that high Pay is valued about equally at all educational levels, but that Security is stressed much more often by the least educated. Such a finding makes good intuitive sense, and leads us to hypothesize that the closed form produces more valid information than the open form about the relation of Work Values to education. This interpretation also accounts for the unexpected overall increase in Security responses on the closed form.¹⁰

Furthermore, there is another piece of evidence suggesting that the closed form may be superior to the open. Satisfaction is the one category that appears with high frequency on the open form but which we did not include on the closed form because it seemed an inferior type of response, almost a tautology (e.g., "I would prefer work that is satisfying"). However, if that

¹⁰ Form comparisons also were made using a four-category occupation variable (professional and managerial, clerical and sales, skilled workers, operatives and unskilled). Results are similar in nature and strength to the tables that employ education, leaving unsettled the extent to which the results depend on cognitive as against positional factors.

Table 5. Work Values by Education and Form: Experiments IIa and b

	Closed			Open		
	0-11	12	13+	0-11	12	13+
1. Pay	13.8%	15.9%	11.0%	20.0%	20.0%	12.8%
2. Accomplishment	11.1	28.4	44.4	6.2	8.0	24.3
3. Autonomy	8.4	8.9	15.9	3.1	3.4	6.5
4. Pleasant	24.5	23.9	14.1	14.8	15.7	13.2
5. Security	36.0	20.0	12.4	4.8	11.1	6.9
6. Advancement	—	—	—	0.0	0.9	1.8
7. Free Time	—	—	—	1.0	2.3	1.6
8. Conditions	—	—	—	3.8	4.0	2.2
9. Benefits	—	—	—	2.8	3.1	1.6
10. Satisfaction	—	—	—	10.0	14.6	19.5
95. Specific Jobs	—	—	—	8.3	3.7	1.2
96. Multiple Responses	—	—	—	3.1	4.6	4.1
97. Other	0.4	0.5	0.4	6.9	2.9	1.8
98. DK	1.9	0.5	0.2	7.2	2.3	0.2
99. NA	3.8	1.9	1.6	7.9	3.4	2.2
	99.9	100.0	100.0	99.9	100.0	99.9
N	(261)	(415)	(498)	(290)	(350)	(493)

were the case one would expect Satisfaction to relate negatively to education, as does mention of a Specific Job (category 95). Instead, Satisfaction shows a clear positive relation to education—in fact one that parallels the relation of the Accomplishment category to education on both forms. Later examination of 100 open responses from Experiment IIa revealed that a number of those coded into Accomplishment had begun by mentioning “satisfying work,” which was then elaborated to spell out the Accomplishment emphasis when probed. We now think that the open Satisfaction category consists primarily of vague and inadequately probed responses representing mainly the Accomplishment value, although occasionally some other value such as Pleasantness, and that this is clarified on the closed form when specific categories are offered to respondents. There is indeed some direct evidence that most respondents in the open Satisfaction category would choose Accomplishment on the closed form. A small subsample of respondents to the open version of the Work Values question in Experiment IIa were reinterviewed six months later and asked a three-category closed Work Values item (see fn. 3 and fn. 11). Of the 26 persons who originally were coded in the open Satisfaction category and later reinterviewed, 69% chose Accomplishment on the reinterview closed question. This is a

much higher figure than for any other group of reinterviewed respondents except those who initially gave Accomplishment itself (which was 83%). Thus people who are coded into the Satisfaction category on the open form tend to choose Accomplishment on the closed form.

Sex. Unlike Education, sex produces very similar patterns on the open and closed Work Values forms in Experiment IIa and b combined. Men are more likely to choose Autonomy and women to choose Pleasantness on each form. There is a trend for men to choose both Security and Pay to a greater extent on the open form, but the overall three-way interaction reaches only borderline significance ($X^2 = 9.1$, $df = 4$, $p < .10$) and is not replicated in data from other experiments.

Unemployment. One further variable was introduced into Experiment IIb in an effort to provide a critical test of whether the open or closed results for the Security category percentage were more valid. At the end of the interview we asked respondents whether they had been unemployed and looking for work at any point in the past five years. We assumed such an experience would be an important stimulus to giving the Security response, and that therefore the form showing a higher association between Security and unemployment could be viewed as having greater claim to validity. For example, if the open question reflects salience in the sense of

personal importance, then its Security category should show the stronger relation to experience with unemployment. Whatever the merits of this reasoning, the test failed, for actual unemployment experience (reported by a fifth of the sample) is not related to the Security response (or to any other category) on either form.¹¹

Conclusions from Work Values Experiments

We believe the initial discrepancies between the open and closed Work Values questions were partly due to the fact that the closed categories were not sufficiently developed from open responses. Alternatives were included that were not within most respondents' frame of reference for the question, while other alternatives were omitted that were important to many respondents. The revised set of closed alternatives developed for Experiments IIa and b retain quite well Lenski's original theoretical goals, yet at the same time

serve to represent more adequately and for more general purposes the work values that respondents offer spontaneously.¹²

Once so developed, however, we think the closed form of the question is superior because it separates types of responses that were often indistinguishable in the open coding (those emphasizing high income and those stressing steady income), while at the same time it merges responses (Accomplishment and Satisfaction) that the open coding tends to separate because of nonsubstantive verbal differences in expression. Whatever the advantages of the open question for assessing salience and for avoiding social desirability effects—and we have been unable to discover firm evidence that either of these advantages actually occurs—there seem to be even greater disadvantages arising from vagueness of expression by respondents, frequent failures to probe adequately by interviewers, and occasional misunderstanding by coders. All this is avoided in closed questions, where respondents are in essence asked to code themselves, with minimal intervention by third parties. In sum, while open questions seem essential for obtaining the frame of reference of respondents and for wording alternatives appropriately, once this is done we are unable to find any compelling reason to keep the open form for the Work Values question. Finally, it will be recognized that these conclusions are suggested, rather than rigorously demonstrated, by the previous results,

¹¹ Two further special analyses will be noted briefly. First, the reinterview data mentioned in fn. 3 were used to study the large number of inadequate responses (DK, NA, mentions of particular jobs only) on the open form. Of the 23 missing data cases from the original open question who were reinterviewed, over 60% chose Pleasantness on the reinterview three-category closed item and only 4% chose Pay. This is significantly different from an expected random distribution of 1/3 in each category ($X^2 = 7.7$, $df = 2$, $p < .05$), and thus it does not appear that respondents who provide missing data on the open form contribute mainly random error on the closed form.

The three-category Work Values closed question (SRC-77August) was itself part of a further experiment to determine what happened when only the three most frequently used categories from Experiment II (Pay, Accomplishment, and Pleasantness) were included in the closed form. Detailed results are not presented here because we now think that the attempt to reduce the closed Work Values item to three categories was a mistake, since it lost the important distinction between Pay and Security. However, it is worth noting that the Pay category in this experiment is negatively associated with education on the closed as well as on the open form, as would be expected once the Security alternative is eliminated and such respondents move into the Pay alternative—a demonstration that relationships to these choices are partly a function of the exact set of alternatives offered. This experiment had one other useful feature, a further test for order effects among the closed alternatives; again the results are negative ($X^2 = 2.4$, $df = 4$, n.s.).

¹² At a late stage in this research we discovered that the closed Work Values question employed by Lenski (1963) is almost identical to one used in a 1954 Consumer Behavior study by the Survey Research Center, except that the earlier version included as a sixth alternative "Income is steady" (Boulding, 1960)! Moreover, unpublished pretests for that study suggest that an alternative referring to liking "the people one works with" also was considered for inclusion at one point, possibly on the basis of earlier open interviewing. Thus in a sense our experiments have led to restoration of alternatives dropped out by previous investigators without sufficient documentation (or perhaps full awareness) of why these decisions were made. Other survey inquiries into work values also occurred during the forties and fifties (see Hyman, 1953), but they differ in wording too greatly from the Lenski item to be directly relevant to our experiments.

and are stated here in a forthright fashion for heuristic purposes.

EXPERIMENTS ON TWO OTHER QUESTIONS

In addition to the sequence of experiments on Work Values, we carried out experiments on two other questions. Neither was pursued to the same extent as Work Values, partly because of limited resources but also because problems arose that are quite instructive from the standpoint of the open/closed controversy.

Most Important Problem

The Work Values item was originally a closed question, and our experiments concerned what happened when an open version was asked. The Most Important Problem question, on the other hand, is one of the very few regularly posed in open form in surveys. It is used in both Gallup Polls and ISR Election Studies to determine the relative importance of issues for the general public. We drew on the 1974 Election Study open code results to construct a closed item with eight alternatives, and both it and a parallel open version were administered as part of the DAS-76 survey.¹³ Univariate results by form are shown in Table 6.

Of the eight common categories only three (Crime, Inflation, and Unemployment) produce appreciable proportions of respondents on the open form but for these the form comparison is quite interesting. Inflation and Unemployment yield essentially the same proportions on both forms, despite the fact that the open form spreads responses among more categories. But the Crime and Violence category attracts more than twice as many respondents when it is offered explicitly on the closed form as when it is coded from spontaneous answers to the open form. Indeed, on the closed question,

¹³ These could not be the first questions in the questionnaire, but most of the preceding questions dealt with irrelevant issues. The one prior mentioned (crime) that might have affected open responses does not appear to have done so, since it is the closed rather than the open form that produced a high crime percentage.

Crime is clearly the leading problem, while on the open form it is second to Unemployment. A review of the non-common open codes suggests that some "crime" responses may be going into other categories (9, 10, and 13 in Table 6), in which case the open question shows that Crime has a number of different meanings in the minds of respondents, whereas the single closed alternative collects these under a single rubric. However, even lumping together all these possibly relevant open categories does not eliminate the significant open/closed Crime difference, and another explanation is needed. A quite plausible though untestable one is that the reference in the open question to "in this country" discourages respondents from including crime, since crime is perceived by many as a more local problem. Although the same constraint appears in the wording of the closed question, provision of Crime and Violence as an alternative obviously legitimizes it there. Thus, paradoxically, the open form of the question produces the narrower frame of reference in this case, and of course if the explanation is correct the open question seriously underestimates public concern over crime.¹⁴

The winter of '77: unforgettable or easily forgotten? After discovering form effects for the Most Important Problem question in the DAS-76 survey, we proceeded to construct a new closed item less susceptible to these effects, though we did not attempt to change the national frame of reference. We picked from DAS-76 the five most frequently given categories of open responses: unemployment, crime, inflation, quality of leaders, and breakdown of morals and religion. These were also essentially the five most frequent closed choices, although not exactly in the same order. The five were included as the

¹⁴ We also examined three-way interactions with sex and education, finding them both significant ($p < .05$). For sex, the main source of interaction is that women give disproportionately more Crime responses on the open than on the closed form, whereas men do not. For education, the closed form shows that more years of schooling is positively related to choosing Inflation and negatively related to choosing Crime, whereas education is unrelated to the open categories.

Table 6. Most Important Problem: Experiment 1^a

Closed Question		Open Question	
Which of these is the <i>most</i> important problem facing this country at present?		What do you think is the <i>most</i> important problem facing this country at present?	
1. <i>Food and Energy Shortages</i>	6.0%	1. <i>Food and Energy Shortages</i>	1.7%
		Natural resources problems, e.g., "not enough fuel," "ecology," "overpopulation."	
2. <i>Crime and Violence</i>	34.9	2. <i>Crime</i>	15.7
		Public order problems, e.g., "courts are too easy on criminals."	
3. <i>Inflation</i>	12.6	3. <i>Inflation</i>	13.3
		High prices, e.g., "increases in the cost of living."	
4. <i>Unemployment</i>	19.7	4. <i>Unemployment</i>	19.1
		Lack of jobs, e.g., "too many out of work."	
5. <i>Decreased Trust in Government</i>	9.9	5. <i>Decreased Trust in Government</i>	3.0
		Lack of confidence in government generally, e.g., "people don't think the government will do what is right," "The people aren't behind the government."	
6. <i>Busing</i>	1.1	6. <i>Busing</i>	1.1
7. <i>Breakdown of Morals and Religion</i>	9.2	7. <i>Breakdown of Morals and Religion</i>	5.7
		Loss of traditional morality, e.g., "family disintegration," "alcohol, drugs, and sex," "turning away from God."	
8. <i>Racial Problems</i>	1.6	8. <i>Racial Problems</i>	2.4
		Majority-minority group problems.	
		9. <i>Quality of Leaders</i>	7.0
		Dissatisfaction with behavior of officials, e.g., "crooked politicians," "government officials who commit crimes."	
		10. <i>Characteristics of People</i>	4.6
		Faults and desires of individuals, e.g., "people want too much," "greed," "people don't get along with others."	
		11. <i>Characteristics of the System</i>	3.0
		Defects in social structure, e.g., "not enough equality," "the government is too big, inefficient, or unresponsive."	
		12. <i>Supportive References to Welfare</i>	1.5
		More should be done for the less well-off, e.g., "poverty," "hunger," "medical care."	
		13. <i>Unsupportive References to Welfare</i>	0.9
		Too much is done for the less well-off, e.g., "welfare fraud," "the welfare mess."	
		14. <i>National Defense</i>	0.4
		Military security	
		15. <i>Foreign Affairs</i>	0.9
		Relations with other countries.	
		16. <i>The 1976 Presidential Primaries or Elections</i>	4.6
		17. <i>Communism</i>	0.7
		Unspecific references.

* Carried out in DAS-76.

closed alternatives in a new experiment in February of 1977, with a parallel but more extended list making up the codes for an open form of the question. Among the possible DAS-76 closed alternatives *not* carried over into the new experiment was "food and energy shortages," since only eight people out of 460 had mentioned such a problem spontaneously in the DAS-76 survey.

The best-laid plans of both the country and the present investigators were disrupted when just as our 1977 telephone survey commenced, the eastern half of the United States was struck by the coldest winter in recent history. Buffalo, New York, became a symbol of other hard-hit cities, factories were shut down in a number of areas, and there were fears of widespread shortages of natural gas. During the 35 days our survey was in the field, *The New York Times* carried 62 stories on the cold spell and its implications, eight of the stories on the front page. This sudden reemergence in a new form of the energy crisis could manifest itself easily on the open version of our question: the "food and energy shortages" code recorded these concerns by making that category the second highest (22%) after Unemployment (29%) and ahead of Inflation (16%). The closed form of the same question, on the other hand, was impervious to the winter events, since only a single person (coded "Other") out of 592 respondents mentioned the energy crisis; the five fixed alternatives account for over 99% of the substantive answers

given. The results bring home an obvious and yet profound point about survey questions: almost all respondents work within the substantive framework of priorities provided by the investigators, whether or not it fits their own priorities.¹⁵

The migration of respondents on the open form into the Food and Energy code is by no means drawn in equal proportions from the five categories common to the two forms. Inflation and Unemployment retain nearly the same percentages on the open question as on the closed question. Much diminished, however, are the percentages of respondents giving Crime, Poor Leaders, or Breakdown of Morals types of responses. Unfortunately, interpretation of these differences is compromised by possible questionnaire context effects. Both inflation and unemployment were queried in the beginning of the 1977 interview, and it is conceivable that this accounts for the maintenance of their proportions, whereas the other open categories virtually disappear. Because of this problem, together with the effects of the unusual winter, we shall not present a detailed analysis of these SRC-77/February data. They do provide a dramatic lesson, however, in the differences produced by question form when external events

¹⁵ This is less true of nonsubstantive responses such as DK. As documented elsewhere (Schuman and Presser, 1978), respondents show considerable willingness to say DK when confronted with issues they know nothing about, though presence of an explicit DK raises the number appreciably.

affect answers. A historian searching opinion poll data for effects of the 1977 severe winter would find them clearly in results based on our open question. The closed form of the same item shows not a trace of the events of that winter. Conceivably an investigator could argue for using either question form depending upon the goals of the research, but it is evident that these goals had better be clear to both writer and reader, for they are not only goals but major constraints as well.

Values for children. A question on preferred values for children provided the basis for our third attempt at open/closed experimentation. But in this case we did not move beyond the initial comparison in DAS-76 because the discrepancy between open and closed distributions was too large, and the spread of open responses too great, to allow reconstruction of an adequate closed question. As Table 7 shows, 99% of the closed responses fall into categories of the original closed question (taken from Lenski, 1963), but only 9% of the open responses are accommodated by these same categories. Moreover, the modal closed response "To think for themselves" attracts 60% of the respondents on that form, but only 5% are coded into the comparable category on the open form.

Eleven additional open categories were used to handle the spontaneous open responses, not counting a relatively large (9%) residual category of miscellaneous "Other" responses. The new categories are of three kinds. At one extreme, a number of legitimate responses involving religious and moral qualities appear that are not readily covered in any way by the closed question. At the other extreme, it is easy to see how certain open categories (e.g., "To be self-reliant") could be assimilated into existing closed alternatives ("To work hard" or "To think for themselves"), though with some loss of the original meaning. Finally, the largest category of the open codes, "To get an education," seems to involve a misinterpretation of the purpose of the question by respondents; it thus illustrates the point occasionally noted (e.g., by Campbell, 1945) that open questions, lacking the additional cues of fixed alternatives, may need to be

more clearly focused than closed questions.

CONCLUSIONS

Not every closed attitude question can be asked in a parallel open form. In fact, in searching for questions useful for experimentation, we found most closed items unsuitable for transformation into open form. Of course, respondents always can be asked to discuss a general topic, and likewise it is almost always possible and useful to ask an open follow-up to a closed item, but neither of these provides a truly parallel form. It is probably no accident that the questions we settled on involved multiple nominal responses to broad inquiries about values and problems. These are the types of questions that one initially thinks of in open form, then closes largely for practical reasons having to do with ease of administration, coding, and analysis. By the same token though, they are the questions where a comparison of forms is most urgent, since the transformation typically assumes that the two forms yield essentially identical results.

Our data show that this is certainly not true in any simple way as far as univariate findings go. Every comparison we made revealed statistically significant and substantively important differences in marginal distributions between open and closed forms. Likewise, most previous experimental comparisons, though rather specialized in type of question tested, also show important differences by form: Blair et al. (1977), Dohrenwend (1965), Marquis et al. (1972), Rugg and Cantril (1944). Our own investigation adds to this previous research three examples of complex questions more typical of current attitude surveys—in one important case investigating the differences through repeated reconstruction of the closed categories. We also demonstrate that open/closed form differences extend to the nature of associations with important background variables as well; in particular, the relation of education to a distinction between "high pay" and "steady pay" in Work Values differs meaningfully depending

^a Carried out in DAS-76.

upon which form of the question—open or closed—is used.¹⁶

¹⁶ The one previous report of such interactions that we have located is by Robinson and Rohde (1946). However, when their tables are reanalyzed using recently developed statistical techniques (Goodman, 1971), none of the reported three-way interactions approaches significance.

It is not possible at this point to draw definitive conclusions about when open/closed differences will occur or whether one form will always be more valid than the other. But our findings do suggest several propositions that are at once tentative conclusions and hypotheses for future research.

1. Form differences will be minimized if investigators begin with open questions on large samples of the target population and use these responses to construct closed alternatives that reflect the substance and wording of what people say spontaneously. This point is so obvious as to be embarrassing to state, yet it is probably violated in survey research more often than it is practiced. Of course, there may be times when an investigator deliberately wishes to exclude frequently given alternatives or add others, but this should be stated and justified explicitly. Otherwise we risk having respondents confirm our own frame of reference without even being aware of it. The "energy shortage" result is a simple and dramatic example of this phenomenon, but the omission of Pleasantness as a possible closed Work Values alternative from the original Lenski (1963) question is perhaps a more important and realistic instance.

2. Where open and *properly constructed* closed forms of questions do differ, it appears that in at least some cases the latter may be more valid—where valid means correctly classifying respondents and correctly describing relationships. For the Work Values question, the reconstructed closed form allows an important distinction to emerge that is obscured on the open form, and shows the distinction to have construct validity in terms of other relationships. In addition, the closed form eliminates a large open category that seems in retrospect to have been due more to vagueness of response than to substantive distinctiveness. In the Most Important Problem question, the open form probably limits some respondents to a frame of reference not intended by investigators, while just the opposite happens in the open form of the Child Values question, where the largest open category ("To get an education") is outside the desired frame of reference. Closed forms of the two questions avoided both these problems. And of course there are many missing data (e.g., multiple responses) to open questions that are eliminated entirely by adequate closed versions. Yet it will not do to say that closed forms, even where carefully constructed on the basis of open responses, are generally superior.

Table 8. Mean Percentage Differences for Common Categories by Education^a

Experiment	Education		
	0-11	12	13+
Work Values I	9.7	14.2	4.9
Work Values II	12.5	8.1	6.0
Work Values III ^b	12.7	12.5	8.0
Important Problem I ^c	14.4	6.8	7.2
Child Values	16.1	10.0	4.7

^a Using common categories only, we calculated absolute percentage differences between the two forms for each category and then averaged these to give the figures in this table.

^b This experiment is described in fn. 11.

^c The second Important Problem experiment was not included in this analysis because of the likelihood of strong context effects, as noted in the text.

Certain important form differences for the Child Values question have not been successfully interpreted, and the issue of whether adequate closed questions are always more valid remains unsettled and in need of further research.¹⁷

3. Some important findings do remain constant across form. For example, Accomplishment as a Work Value is positively related to education in all of our experiments, despite differences in form, in wording, and in the number and nature of the other alternatives present. There is thus a robustness to the relationship that simply does not hold for other associations equally interesting and equally significant statistically in particular analyses. An investigator should probably feel more confidence in the meaningfulness of such a stable finding.

4. Open/closed differences appear to be smaller for some parts of the population than for others, in particular for more

¹⁷ What little evidence exists in past literature on the issue of validity is mixed. The strongest such study is by Blair et al. (1977) and provides fairly persuasive evidence for the superiority of the open form in eliciting quantitative reports of drinking and sexual behavior. Two of the coauthors of that study summarize elsewhere certain circumstances in which they believe open questions to be generally more valid (Sudman and Bradburn, 1974). On the other hand, Marquis et al. (1972) present evidence in favor of closed questions, though their results are based on a special factual situation. Finally, Dohrenwend (1965) offers results indicating that closed questions are superior in certain respects, but her investigation involved an experimental situation remote from typical attitude surveys and does not seem to have standardized the questions employed.

educated as against less educated respondents (see Table 8). This is largely due to the fact that the least educated bulk disproportionately large in open missing data categories, and it is these responses that must, in a sense, be redistributed when the closed question is asked. Nevertheless the effect is real in terms of creating a greater gap between open and closed results for less educated respondents than for the more educated.

Finally, since our results fail to provide strong support for the superiority of open questions, the implication may seem to be that after sufficient pilot work an investigator can rely exclusively on closed items. But we think that total elimination of open questions from survey research would be a serious mistake. For one thing, open questions may be needed to document the *absence* of a type of response, as in Stouffer (1955) and Converse (1964), though as we have seen, care must be taken that the wording of the open question does not subtly prevent the emergence of relevant types of responses. Open "why" questions can also be especially useful as follow-ups to important closed questions, providing insight into why people answer the way they do (see Crutchfield and Gordon, 1947; Schuman, 1966; 1969). Open questions also are needed where rapidly shifting external events can affect answers, or indeed over longer stretches of time to avoid missing newly emergent categories. And of course in some situations the set of meaningful alternatives is too large or complex to present to respondents—a serious problem with telephone surveys where cards are not possible.

Furthermore, as survey data come to provide the material for history, open interview responses take on increasing value because they allow future social scientists to create in retrospect new categories undreamt of by the original investigators—to put, in effect, new questions to one's predecessor's respondents. Consider that remote ancestor of present-day research, the Domesday Survey, carried out in 1086 with William the Conqueror the Principal Investigator. The new king was less interested in the attitudes of his subjects than in their holdings;

but supposing he had obtained a representative sample of public opinion in the late eleventh century, we would find its value considerably greater if what were preserved were the spontaneous thoughts and language of men and women of those days, rather than simply choices among alternatives A, B, and C. The same will not be less true in our own time, and investigators with a concern for the future should make certain that more than numerical codes are transmitted to social scientists of the next decade, century, or millenium.¹⁸

¹⁸ This assumes that responses are recorded with substantial accuracy, of course, and that these raw responses are available for later recoding. As Duncan et al. (1973:36) discovered, use of earlier open coding results can be quite misleading. Even where the goal is only to study social change via exact replication, it is important for all sets of responses to be coded by the same set of coders (if possible blind to the sources of the responses), lest changes in coding practices be mistaken for changes in respondent attitudes. New methods of electronic recording of verbal responses should make storage much easier in the future.

ERRATA

■ Errors occurred in the article, "Class Power and State Policy" (ASR, June, 1978) by Alexander Hicks, Roger Friedland and Edwin Johnson. In Table 2 on page 30 inaccurate correlations appeared for the following pairs of variables: X_6 and Y_4 (.59); X_7 and X_4 (.45); X_6 and X_7 (.23); Y and X_6 (.47). The correct correlations are: X_6 and X_4 , .45; X_7 and X_4 , .59; X_6 and X_7 , .21; and for Y and X_6 , .48.

■ In the article, "Making It in America" (ASR, June, 1979) by Stanley Lieberman and Donna Carter; the occupational materials on page 365 should have appeared under Table 4 (page 359) as part of the second footnote to that table.

THE ANALYSIS OF OPPOSITIONAL STRUCTURES IN POLITICAL ELITES: IDENTIFYING COLLECTIVE ACTORS*

EDWARD O. LAUMANN

American Sociological Review 1979, Vol. 44 (October):713-732

In this paper we propose a theoretical rationale for characterizing oppositional structures in political elites. Concepts currently used in the study of political conflict suffer from serious theoretical and empirical deficiencies. We therefore introduce the concept of a *collective actor*, which we treat as an elementary analytic unit in the study of conflict structures in elite systems. We then develop a set of spatial models describing the alternative forms of oppositional structure that have received attention in the literature. Finally, we attempt to demonstrate the utility of our approach in a comparative analysis of two quite different community elite systems.

In this paper we propose a theoretical rationale for characterizing oppositional structures in political elites. Concepts currently used in the study of political conflict suffer from serious theoretical and empirical deficiencies. To circumvent some of these difficulties, we introduce the concept of a *collective actor*, which we treat as an elementary analytic unit in the study of conflict structures in elite systems. We then show that when considered across a range of issues, overlapping memberships of collective actors may be used to describe the nature of the cleavage structure within a system of collective action (cf. Coleman, 1973; Marsden and Laumann, 1977). Finally, we present one method of operationalizing the collective actor concept, and illustrate its application with data from two community leadership studies.

We have discussed elsewhere various

conceptions of structure in community decision making (Laumann et al., 1977:595-8; see also Hunter, 1953; Dahl, 1961; Rosē, 1960; Walton, 1966; Clark, 1968a; and Aiken, 1970). The element common to all of these conceptions is an assumption that regularized linkages of communication among elite members are required for the effective resolution of local issues. Accordingly, virtually all recent work in this area has been concerned with analyses of social networks in which decision makers are implicated (Laumann and Pappi 1976; Burt, 1977; Marsden and Laumann, 1977; Alba and Moore, 1978; Breiger and Pattison, 1978; Moore, 1979; Breiger, 1979). The trend toward a network approach in this area is, on balance, a useful one. It sometimes has resulted, however, in the uncritical transfer of concepts from other substantive fields into a setting for which they are ill adapted. Before introducing the concept of a collective actor, we will examine these concepts and their connotations.

Order of authorship is alphabetical. A previous version of this paper was read at the International Conference on Mathematical Approaches to the Study of Power, Bad Homburg, West Germany, March, 1978. Writing was supported by a grant from the National Science Foundation, NSF SOC77-26038. We appreciate the assistance of Lynn Appleton, James Burk, and Margaret Troha in performing the data analysis and in commenting on previous drafts of the manuscript. We also wish to acknowledge our debts to the following colleagues who have provided criticism and suggestions: Charles Bidwell, Charles Cappell, Terry N. Clark, James S. Coleman, Noah Friedkin, Morris Janowitz, Franz U. Pappi, Arthur Stinchcombe, Christopher Winship, and Rolf Ziegler.

Concepts in Use for the Study of Political Conflict

Six major concepts have been proposed as elementary units for the analysis of political conflict: cliques, social circles, quasi-groups, action sets, factions, and coalitions. Each of these differs from the others in certain important respects. They, however, can be ordered along a continuum giving the degree to which each is oriented to the attainment of ap

explicitly stated goal. A second feature that distinguishes the six concepts is the degree to which the network characteristics of the elementary unit are stressed.

The concept of *clique* has been the starting point for many efforts to adapt network approaches to conflict analysis. A clique is a set of persons directly linked to one another via mutual relationships (Alba, 1973; Burt, 1978). In terms of graph theory, a clique is a maximally complete subgraph (Luce and Perry, 1949). The clique concept was developed by social psychologists interested in well-defined small populations of actors, such as students living in dormitories, soldiers in barracks, or workers on an assembly line. Such persons typically are involved in recurrent informal interactions, often involving deeply felt interpersonal sentiments. Drawing on experimental research demonstrating the effects of group norms on perception (Sherif, 1936; Asch, 1951) as well as observational studies showing the effects of social pressures within intimate contexts (Whyte, 1943; Newcomb, 1961), studies have argued that dense communication networks engender similarity of perceptions and opinions among their members. Applied to elite analysis, the implication of this is that linkages of friendship or communication among elite members also breed interest similarity (see Domhoff, 1970:chap. 4).

The difficulty here is that the contacts that elite members have with one another serve a variety of diverse functions. Some of them may be used to build or maintain social solidarity among persons committed to a particular political stance. A community elite, however, may be regarded as an informally elaborated institution that provides a means for the articulation and resolution of conflicting claims for collective action (Laumann and Pappi, 1976). Contacts among its members therefore provide channels for bargaining and negotiating with opponents to reach broadly acceptable outcomes, and are not merely a device for the organization of conflict groups. If the clique concept were to be used as a general definition of oppositional groups within elites, we should expect to find that persons holding op-

posed preferences would exhibit strong tendencies to avoid one another in constructing their social networks. Our empirical investigations bearing on this point, however, do not reveal such tendencies (Laumann et al., 1977:606-13).

A community elite is not a social group confined within a circumscribed physical setting, as are most of the groups studied in the small-groups tradition. The theoretical and empirical differences contrasting elite systems with naturally occurring or experimentally constructed small groups suggest that interactions of elite members will result in loosely-knit, ramifying networks. The linkages in these networks may involve only modest levels of affect, and often will include important instrumental components. This suggests that these linkages are more likely to result from preexisting interest similarity than to be a foundation of common interests (see Laumann et al., 1977:614). Actors in leadership positions construct their personal networks purposefully, targeting on others whom they perceive both as resourceful and as likely to share their own issue preferences. To achieve their ends, however, they must not neglect the need to maintain contact with elements of the opposition.

Thus, conceiving of the oppositional structure in terms of cliques tends to carry some inappropriate theoretical overtones having to do with the expressive nature of interpersonal attachments among clique members. Furthermore, to analyze networks without respect to outcome preferences is to risk confounding ties oriented to conflict resolution with those oriented to the organization and mobilization of support.

Perhaps in response to some of these difficulties with using the clique concept in analyzing elite structures, Kadushin (1968:esp. 692) proposed the concept of a *social circle* (see also Alba and Moore, 1978).¹ The definition of a social circle

¹ A related notion is Kadushin's (1976) concept of a power and influence circle. One additional reason for modifying the definition of oppositional groups in terms of cliques is that meaningful groups meeting all the defining characteristics of cliques rarely are discovered empirically (see Sonquist and Koenig, 1976; Alba and Moore, 1978).

specifies that members must be sociometrically linked with one another, but does not require that all pairs of members be *directly* linked as the clique concept does.² Thus, rather sparse networks may qualify as social circles. Additionally, it is required that members of a social circle share common political or cultural interests, broadly conceived.

The notion of a social circle is a useful step toward an appropriate definition of oppositional units, in that it relaxes the stringent criterion of dense connectedness required of cliques and takes some account of concerns that might serve as a basis for disputes among elite members. It is not fully appropriate for analyzing conflict, though, because Kadushin explicitly specifies that a social circle has no clearly defined goals. The "interests" to which the concept refers are evidently not specific outcome preferences, but instead vague expressions of concern about certain issue domains (e.g., foreign policy, cultural affairs), combined with a willingness to engage in discussions pertinent to these topics (see Barton et al., 1973; Kadushin, 1974; Alba and Kadushin, 1976). Social circles are therefore more descriptive of the organization of particular issue arenas (Clark, 1968a:67-72; Freeman, 1968) than of the contending oppositional groups *within* these arenas.

Two other concepts, the *quasi-group* and the *action set*, are offered in the anthropological literature. Mayer (1966) develops two types of quasi-groups. One type, the interactive quasi-group, refers to a purposively constructed egocentric network, and hence cannot be used in the analysis of group structure. The second type, the classificatory quasi-group, is essentially a category of persons sharing common interests without any definite social organization. Both interests and social organization, in our view, need to be considered in the analysis of oppositional structures.

² Alba (1973) proposed another concept, the *n*-clique, that also relaxes the connectedness criterion for cliques, and substitutes the requirement that persons in an *n*-clique be linked to one another via directed paths of, at most, *n* linkages. In later work, however, this concept is discarded in favor of the social circle (Alba and Moore, 1978:178).

The idea of an action set (cf. Boissevain, 1974:170-205; Aldrich, 1979:280-1, 316-21) is somewhat more promising. An action set is a group of actors who form a temporary alliance in pursuit of a strictly delimited purpose. This concept directs attention both to the interconnectedness of actors and to the *active participation* of members of the action set in realizing a common goal.

Two final concepts, *faction* and *coalition*, are most commonly employed by political scientists. Key (1949:16) defines a faction

to mean any combination, clique, or grouping of voters and political leaders who unite at a particular time in support of a candidate. Thus, a political race with eight candidates will involve eight factions of varying size. Some factions have impressive continuity while others come into existence for only one campaign and then dissolve.

This usage of the term has the virtue of directing attention to conflicting, specific goals toward which actors are oriented, but it does not explicitly characterize the social organization of the group. It also is restricted, by this definition, to the study of electoral opposition.

Some similar comments pertain to the term *coalition*. There is no consensus on a rigorous definition of this concept (Gamson, 1968), but it typically emphasizes the rationalistic calculation of advantage by individualistically oriented actors in legislative or electoral behavior. Riker's (1968:524) definition illustrates:

[A coalition is] . . . a group of people who come together (usually on a temporary basis) to obtain some end. Typically, a coalition has been regarded as a parliamentary or political grouping less permanent than a party or a faction or an interest group.

Thus, coalitions involve only those actively engaged in pursuing their objectives, at least insofar as each person must cast a vote. They include only actors sharing common interests, though coalition formation also may be constrained by strategic considerations. For instance, the size of a coalition may be limited to the minimal number of members required for success, so that payoffs to members from effective joint action can be maximal (Riker, 1962). In any case, the resultant

coalitions are more in the nature of voting blocks or categories than groups having a definite social organization.

If the clique concept exaggerates the importance of personal relations for the construction of common interests for elite members, the ideas of coalition and faction err in the other direction by ignoring or minimizing the social structural conditions for group formation among those having shared objectives. Of course, the delimited physical setting in which legislators operate is one that guarantees contact between even the most improbable coalition members. In addition, the formal nature of membership in such collectivities makes it certain that all actors in a legislature are aware of potential partners for coalitions. It is thus arguable that the importance of specific communication channels can be deemphasized in analyzing coalition formation within legislatures or other formally constituted deliberative bodies. This is a very special case, however, and in other circumstances, elite members may be geographically and socially dispersed. In fact, even membership in an elite system or activation on a specific issue episode may not be sharply defined. For these reasons, we see a need for a new concept for the study of elite cleavage structures.

Collective Actors As Units in Oppositional Systems

In our survey of concepts used in the study of political conflict, three major components of the various definitions have been identified: (1) degree of social *cohesion* among group members; (2) the degree to which a well-defined *preference* or purpose is shared among group members; and (3) the degree to which group members *actively participate* in pursuing this purpose. We have found the concepts of clique and social circle inadequate because they focus on social cohesion to the exclusion of preference. We have criticized the concepts of faction and coalition because, while drawing attention to preferences and activity, they largely ignore the sociological question of internal group structure.

Clearly any adequate definition of a

conflict group must include both the elements of cohesion and preference. The crucial question for us is whether it also should include the third component listed above, participation. Note, first, that a convenient feature of elections and legislatures, the sorts of systems most frequently studied by political scientists, is that there is a clear, unambiguous act, voting, that signifies participation (cf. Stinchcombe, 1975:558). The circumstances involved in the study of other elite systems are quite different. Instead of the simultaneous statement of participation and preference through the vote, we are concerned with a more diffuse process of influence mobilization and persuasion. Diverse acts, such as public expressions of support in the mass media, solicitation and donation of funds, or organization of ad hoc committees, as well as legally authoritative acts like voting or the issuing of administrative directives, may have substantial consequences for the outcome of a contested issue. Not all of these acts will necessarily be defined as participation by the actors themselves or be regarded as legitimate by the community at large.³

We contend that there is a fundamental ambiguity to the notion of participation in an influence system. There is not always a common "metric" in terms of which acts of "participation" can be defined and rendered comparable to one another (cf. Parsons, 1969). Instead, the nature of an influence process in an elite system is one in which the informal networks linking individuals serve as channels by which opinions are privately transmitted, or as devices through which supporters of a given position come to know the extent of their "latent" support among other leaders. Furthermore, to specify active participation as a criterion of membership in a conflict group is to bypass one of the most crucial questions having to do with collective action: the question of the condi-

³ For instance, an industrialist who wishes to influence a zoning decision because of its bearing on his firm might be ill-advised to identify himself publicly as a member of a coalition which included the chairman of the zoning commission. Other less overt acts might be far more effective toward the achievement of his objective.

tions and processes which produce active participation (Olson, 1965).

For the above reasons, we propose the following definition of a *collective actor*, a new concept that is to serve as an elementary analytic unit for the oppositional structure of a collective decision-making system. A collective actor is defined as the set of all members in an elite decision-making system who (1) share an outcome preference in some matter of common concern, and (2) are in an effective communication network with one another. A collective actor thus constitutes the *maximal opportunity structure* for coalition formation on a given issue.⁴

Several observations about this definition should be made. First, we explicitly intend to include in a collective actor only those persons who subjectively share a preference for a specific issue outcome. We, however, do not require that *any* of them be "actively involved" in the resolution of the issue. It is possible that no member attempts to exert influence in any fashion. The collective actor, in this case, would be a latent group, since its members would possess two necessary but not sufficient conditions for collective action, shared preferences and preexisting communication channels. The interesting question, of course, suggested by this feature of the definition is that of the conditions under which the persons in a latent group will in fact become activated. Certain attributes of a collective actor, such as size, density of communication contacts, or resources controlled by its members, might be shown to influence the likelihood and character of its participation in a controversy.

A second observation is that in defining an "effective communication network," we require that all members of the collective actor be mutually reachable but not necessarily adjacent. We thus relax one of

the stringent criteria for defining a clique in favor of a more flexible condition, like that used in defining a social circle.

Because of the requirement of shared preference, membership in a collective actor is mutually exclusive of membership in any other collective actor on that issue. It is not, however, necessarily exhaustive; influentials who are isolates in a network or hold no outcome preferences for a given issue will not be members of any collective actor for that issue.

Collective actors thus differ in important theoretical respects from other concepts extant in the literature. Cliques, conceived as solidarity groups with enduring interpersonal commitments, may or may not be coincident with collective actors. This is so because collective actors, unlike cliques, are constructed with explicit reference to a commonality of interest. Well-established cliques with strong interpersonal bonds can tolerate situations in which some of their members agree to disagree on a given issue. If our approach is utilized, however, such circumstances would mean that clique members who disagree on an issue would be assigned to opposing collective actors.

It is more difficult to specify the relationship between a collective actor and a coalition, since there is not a generally accepted definition of the latter term. If we accept the definition of coalition given above, in terms of shared preferences, mutual access for communicating intentions, and universal activation, then collective actors are coextensive with coalitions when all of their members are activated. When there is less than complete participation, members of a coalition are a subset of the members of a collective actor. The correspondence between collective actors and coalitions also depends on the way in which the collective actor concept is operationalized. To the extent that the issue around which a group forms is of broad scope and of enduring concern, and to the extent that linkages in the communication network involve stable interaction as opposed to issue-specific discussion, the collective actor comes to appear as a more or less permanent feature of an oppositional structure. It thus moves away from the temporary alliance

⁴ Cook (1977:69) uses the term *opportunity structure* to refer to an egocentric network of possible exchange relations. Our usage differs from hers in two important ways: it describes a collectivity in relationship to an issue, and it refers to a collectivity as a whole, not to a network centered on an individual.

of convenience implicit in the concept of coalition.

Finally, we should note that collective actors do not correspond to the "blocks" or "structurally equivalent positions" recently suggested as analytic units for social networks (White et al., 1976; Burt, 1977; 1978). Collective actors do include one central feature of oppositional roles, shared preferences. There is no requirement, however, that the formal aspects of the personal communication networks be similar for members of a collective actor. In fact, we expect that collective actors typically will include persons who act in various roles, such as organizer, critic, pundit, and so forth (see Nuttall et al., 1968). All of these formally defined roles, however, will be related in that the persons enacting them are in pursuit of a shared objective.

Having defined the elementary units for the study of opposition, we are now in a position to move to the question of how to use them to characterize differing oppositional structures. We consider this issue in the next section.

Characterizing Oppositional Structures

Over the past five years Laumann and his colleagues have been developing a framework for the structural analysis of social systems (cf. Laumann, 1973; Laumann and Pappi, 1976; Laumann et al., 1977). In applying this framework, we must first identify individual *actors* and map them into the *social positions* that constitute the social system under analysis (cf. Parsons, 1951). Next, we may define and analyze a *social structure* as a persisting pattern of relationships among these social positions.

For the case at hand, collective actors organized around various issues resolved over time constitute the set of social positions of concern to us in the analysis of the conflict structure of an elite decision-making system. To proceed to analyze this oppositional structure, we must specify the domain or population of issues to which the structure pertains, and the nature of the relationships between collective actors.

An intuitive way of thinking about re-

lationships between collective actors is to see them as functions of the pairwise similarities and dissimilarities of their constituent memberships. There is, by definition, maximal dissimilarity between the memberships of collective actors identified for a particular issue episode. Since, however, collective actors are to be defined for each distinct issue, the degree to which collective actors will overlap from issue to issue is empirically problematic.

Examining overlapping memberships of subgroups of a leadership system is not, of course, an entirely novel endeavor. One frequent indicator of the degree of centralization of an elite is the extent of overlap between the participants in different controversies (Freeman, 1968; Clark, 1968b:580; Grimes et al., 1976:712). We previously have remarked (Laumann et al., 1977:596), however, that measuring overlap of participation without reference to preferred outcome may result in an incomplete or misleading structural description. For instance, a community in which the same persons play an active role in all issue episodes may be one in which a broad consensus prevails on all issue alternatives, or one in which two factions persistently disagree, or one involving shifting coalitions as different issues arise. The approach we propose here is not especially sensitive to participation per se, but it does permit us to discriminate among these different oppositional arrangements because of our definition of collective actors in terms of outcome preferences of their members.

Figure 1 portrays four theoretically possible configurations of collective actors. We have selected them because they can be linked to models commonly discussed in the literature on community power structures. In each of the four diagrams, the location of a collective actor is indicated by a point. The point is labelled by a capital letter with a subscripted *o* or *p*. The capital letter indicates the issue with which the collective actor is concerned, and the subscript tells whether the collective actor is an opponent (*o*) or a proponent (*p*) of the proposed change constituting an issue.

I. Centrally administered model,
no oppositional collective actors

II. Unidimensional oppositional model,
recurrently opposed collective actors

III. Multidimensional cleavage model,
coordinating center absent

IV. Polycentric bargaining model, with
widely scattered opposed collective actors

Figure 1. Four Theoretically Possible Models of the Oppositional Structure of Elite Decision-Making Systems

Model I presents the centrally administered version of an elite decision-making system. Here, the memberships of all collective actors are coincident with one another. There exist no collective actors opposing their dominion over the community. This would be a degenerate case in terms of the operational procedures for modelling the structure to be introduced below, but it would be easily recognized by the complete absence of any "losing" collective actors.

This centrally administered model corresponds to images of structure described as "pyramidal" or "elitist" in the literature. The classic case is, of course, Hunter's (1953) characterization of the power structure in Regional City. Note that it is not the case that all members of this elite were actively involved in the resolution of each issue considered; much overt "activity" involved efforts at implementation by second-level governmental leaders. There was, however, no effective opposition to the "crowd" dictating policy on any particular matter, nor any appreciable dissensus within the leadership as to preferred outcome. Other conceptions corresponding to our notion of a centrally administered model are Rossi's (1960) pyramidal structure and Gilbert's (1968) less pluralistic, elitist power structure.

In model II we have portrayed the polarized community leadership system. Such a system is discussed in Coleman's (1957) article on community conflict, and also is related to our earlier (Laumann et al., 1977:607) depiction of an "oppositional model" for the organization of communication contacts within an elite, and to Gilbert's (1968) notion of permanent factions within a less pluralistic power structure. Here we observe a single dimension of opposition, with clusters of collective actors arrayed at opposing poles of a continuum. The clusters contain collective actors which substantially or completely overlap in their constituent members. This is the situation in which we would expect collective actors to resemble sociometric cliques most closely, because of the consistent separation of leaders into shared oppositional positions,

which may be expected to generate solidarity among them.

Clearly, there must be substantial issue consistency within an elite if the polarized configuration is to emerge in a community. This is likely to be present only in communities in which there is only a single axis of social or economic differentiation (Laumann et al., 1977:624). Furthermore, a condition of stability for this model is that neither faction be continually unsuccessful. With a sharply skewed distribution of success, we would expect a loss of motivation by members of the unsuccessful group, and an eventual transformation of the polarized model into the centrally administered model.

Our third model, the multidimensional cleavage model, might occur in a more highly differentiated community. Model III is distinguished from our other models by two features. First, there are multiple bases for the generation of opposed interests. These serve to define stable oppositional groups within the different issue arenas. The second characteristic of a structure corresponding to model III is an absence of centrally located factions sharing members with a variety of more peripheral collective actors. That is, there is no oppositional unit consisting of actors recruited from diverse areas of community concern, that might be expected to serve as a coordinating center. The collective actors in such a structure would tend to be relatively homogenous in their composition and would be likely to pursue narrowly defined special interests.

In order for model III to be present, there must be *orderly* changes in the composition of collective actors as one moves around the ring in the figure. The members of any collective actor must be divided into subsets that overlap with the memberships of the adjacent collective actors in one direction or the other. A plausible empirical situation which might generate such an arrangement is one in which interests in an area such as health policy shade over into those in "adjacent" areas having to do with people-oriented services like welfare or education, but are unrelated to areas such as land development or transportation. This sort of model

would involve multiple, functionally specialized elites of the type postulated by Keller (1963). Model III is also descriptive of Rossi's (1960) "polyolith" model.

The final model to be discussed is that of the polycentric bargaining structure. This oppositional pattern also arises when there are multiple bases for interest formation. In contrast to model III, however, these bases tend to be unstable and ill-defined. This means that it is likely that at least one of the collective actors for each issue will be composed of quite diverse actors. Such heterogeneous groupings will tend to overlap substantially across issues, and will hence constitute a coordinating central position in the oppositional structure. More homogeneous collective actors representing particularistically defined interests will be arrayed around this core. The peripheral groups tend to resemble coalitions in that their members are activated only on the issue that is their special concern.

This model of multidimensional opposition including a coordinating center resembles images of power structure described as pluralistic, though they refer to a different model of pluralism than that in model III. The studies by Dahl (1961) and Banfield (1961) document situations in which a small number of individual actors participate in a broad range of issues, while coalitions arise around special interests. Model IV might also pertain to Rossi's (1960) notion of caucus rule, or to pluralistic situations described as "fluid alliances" (Gilbert, 1968) or "shifting coalitions."

Operationally Defining Collective Actors

Two decisions are necessary if the collective actor concept is to be used in empirical analyses of elite oppositional structures. One of these involves the selection of the set of issues to which the structure is to apply, and the operational definition of the preferences of individual actors must be mutually oriented to one concerns the definition of an "effective communication network" within the set of individual actors who share a preference.

Both of these elements of the operational definition of a collective actor allow considerable flexibility. We favor the choice of specific, concrete issues for the definition of collective actors, because they narrowly specify a commonality of interest for elite members. Others may prefer a broader definition of issues. There are, of course, several approaches to the measurement of preferences on these issues, however defined (see Clark, 1974; Laumann and Pappi, 1976: 170).

Clearly, there is also some latitude in the operational definition of an effective communication network. Two conditions are nonetheless indispensable here. First, actors must be mutually oriented to one another in a communication network if it is to be regarded as effective. In our analysis, we meet the mutual orientation criterion by specifying that members of a collective actor must be in a single strong component of a digraph,⁵ but others may wish to adopt a more limited definition of an effective linkage between actors, such as that suggested by Alba (1973). Secondly, we would require that the linkages in the network be established *before* the resolution of an issue around which a collective actor is formed, if they are to be used for the organization of collective action.

In the empirical examination of the oppositional structures in two community elites reported below, we use an operational definition of a collective actor as a set of at least three individuals in an elite who (1) share a self-reported preference on a specific issue and (2) constitute a strong component in a digraph formed by taking the union of three intraelite in-

⁵ The mathematical theory of digraphs (cf. Harary et al., 1965:v) is concerned with postulates and theorems relating to "abstract configurations called digraphs, which consist of 'points' and 'directed lines.'" The condensation of a digraph D occurs when one can partition the points in it into disjoint subsets S_1, S_2, \dots, S_k such that a new digraph may be drawn in which there is a line from S_i to S_j if and only if in D there is at least one line from a point in S_i to a point in S_j . The sets of points S_1, S_2, \dots, S_k are the *strong components* of the digraph. Within each strong component, or maximal strong subgraph, a directed path of some length exists connecting each pair of points included in the set.

teraction networks. These networks include an individual's three most frequent contacts with other elite members for (a) business or professional relations, (b) informal social relations, and (c) the discussion of community affairs (cf. Laumann and Pappi, 1976; Laumann et al., 1977).⁶ The requirement of a minimum of three members is adopted as a convenience, to keep the number of collective actors to be analyzed manageable.

An Empirical Examination of Collective Actors in Two Communities

To illustrate the application of the collective actor concept and our methods for the study of oppositional structures, we have analyzed data on elites in two communities we have recently studied, Altneustadt, West Germany, and Towertown, U.S. Both are small cities that serve as distribution centers for surrounding agricultural areas; neither is dominated by a nearby urban center. Each is the site of a large institution—a natural science research center in Altneustadt and a large state university in Towertown. The dominant lifestyle of both communities may be described as middle class (for additional details on the two communities, see Laumann and Pappi [1976]; Laumann et al. [1977]).

In each community, a local elite was identified by the positional-reputational method described by Laumann and Pappi (1973; 1976: 95–100, 270–3). We also selected five local issues for intensive study. Our criteria for issue selection were (1) that each issue studied have a major impact on community affairs in the eyes of our informants, and (2) that there be some diversity in content of issues within the set chosen for each community (see Laumann et al., 1977: 600–2).

In Altneustadt, the issues identified according to the above considerations were (a) relocation of a large industrial firm to the community; (b) construction of a new city hall; (c) incorporation of outlying

communities into an expanded city administrative unit; (d) establishment of a secular primary school as opposed to the existing confessional school; and (e) permission to hold a rock concert in public park lands in the community. In Towertown, the issues studied were (a) construction of a new private health-services center to replace a local public hospital; (b) choice of the appropriate jurisdiction, the city or the county, to administer a proposed new local airport; (c) imposition of a curfew after student disturbances at the university during the Vietnam conflict; (d) choice of location for a new post office, either in an urban renewal area or close to the major downtown banks and businesses; and (e) closing of an experimental school by the Board of Education in favor of reinstitution of a neighborhood-school plan.

The remaining information necessary to identify empirically collective actors is a description of the communication network involving elite members. This was obtained by combining the answers to three questions concerning different types of contact, as noted above (for text of questions, see Laumann and Pappi, 1973: 217n).

Using this information, we identified collective actors in both communities. First, each network was partitioned into groups of individual actors sharing an outcome preference. We then located the strong components in the graphs resulting from the partitioning. This procedure located nine collective actors in Altneustadt and ten in Towertown. We have presented some illustrative data on the network features and compositional characteristics of these oppositional groups in Tables 1 and 2.

The first table presents selected network characteristics of the collective actors identified. Inspection of the table shows that collective actors vary widely on characteristics that have been theoretically and empirically linked to variations in the ways subnetworks function in larger systems by other studies (cf. Mitchell, 1969; Leinhardt, 1977). It would not surprise us to find, for example, that the size of a collective actor might have a strong impact on its likelihood of success. While

⁶ Strictly speaking, our measurement procedures do not allow us to establish with certainty that the linkages between elite members were formed prior to all issue episodes considered, as our operational definition of a collective actor would ideally require.

Table 1. Network Characteristics of the Collective Actors

A. Altneustadt					
Issue	Collective Actor ^a	Size	Density ^b	Maximum Path Distance ^c	Average Path Distance ^d
Industrial Resettlement City Hall	A _p (X)	37	21	6	2.7
	B _p (X)	26	22	7	3.0
	B _{o1}	3	100	1	1.0
	B _{o2}	3	67	2	1.3
Incorporation School	C _p (X)	30	20	7	3.3
	D _p (X)	32	20	8	3.2
Pop Festival	E _p	13	33	5	2.4
	E _{o1} (X)	8	6	6	2.6
	E _{o2} (X)	3	100	1	1.0
B. Towertown					
Issue	Collective Actor ^a	Size	Density ^b	Maximum Path Distance ^c	Average Path Distance ^d
Hospital	A _p (X)	45	18	7	3.2
	A _o	3	67	2	1.3
Airport	B _p (X)	5	67	3	1.8
	B _o	46	19	7	2.8
Curfew	C _p (X)	24	20	5	2.6
	C _o	6	80	3	1.7
Post Office	D _p (X)	14	24	8	3.0
	D _o	18	39	5	2.2
School	E _p	11	75	7	3.9
	E _o (X)	18	11	8	4.2

^a Notation in this column is used to refer to the collective actors in the figures below. An "X" in parentheses indicates that the collective actor was successful.

^b Density is defined as the percentage of possible linkages between members of a collective actor that are actually present.

^c Largest path distance connecting members of a collective actor in a digraph (cf. Harary et al., 1965: ch 5).

^d Mean path distance connecting members of a collective actor.

this "obvious" inference is sustained for Altneustadt ($r_s = .56$), it is not for Towertown, where there is only a slight positive correlation between size and being a winning collective actor ($r_s = .21$).⁷

Three other characteristics of a collective actor, its density of connectedness, its maximum path distance or "diameter," and its average path distance between members, can be quite plausibly linked to its relative organizational facility in mobilizing constituents in support of a particular policy initiative. Unfortunately, respondents were limited to three choices in each of the three relational networks used in the analysis, and this imposes some artifactual constraints on the values of these variables due to the varying sizes

of collective actors. When the number of choices per actor is restricted, it is necessarily the case that larger collective actors tend to have lower densities, and higher maximum and average path distances. The relationships of these network properties to success are thus largely artifactual, owing to size. Despite this, however, we would suggest that the fact that a large network is only loosely and non-redundantly interconnected should place some limitations on its ability to form an effective coalition. Smaller, dense collective actors, in which all constituent members can easily have access to one another, would appear to have some competitive advantage in coordinating their behavior vis-à-vis larger opponents (cf. Lipset et al., 1956; Olson, 1965). Such advantages may be outweighed in the long run, though, by the greater range and quantity of resources that larger collective actors can mobilize.

Table 2 directs attention to variations in

⁷ Because each correlation reported here refers to a very small number of units, we have reported Spearman rank correlations which are less sensitive to outliers. The corresponding Pearson correlations, however, yield identical substantive implications.

Table 2. Compositional Characteristics of the Collective Actors

^a Notation in this column is used to refer to the collective actors in the figures below. An "X" in parentheses indicates that the collective actor was successful.

^b Percentage of members of a collective actor who are primarily active in the business or economic sector. Refer to Table 1 for case bases for percentages.

^c Percentage of members of a collective actor who identify with the dominant political party in the community (in Altneustadt, the Christian Democratic Union; in Towertown, the Republican party).

^d Mean influence rank of members, as determined by the procedure outlined in Laumann and Pappi (1976: 98-100).

^e Percentages of members of a collective actor who are attributed the influence resource of official decision-making authority (see Laumann and Pappi, 1976: chap. 11).

^f Percentage of members of a collective actor who are attributed the influence resource of reputation as a public mobilizer.

^g Percentage of members of a collective actor who were active in the resolution of the issue around which the collective actor is formed. This information is not available (n.a.) for the two hypothetical issues in Altneustadt.

^h Mean number of issues on which members of this collective actor were activated, out of the three issues decided in Altneustadt or the five issues decided in Towertown.

ⁱ Mean standardized score on social egalitarianism scale (see Laumann and Pappi, 1976: 74-9, 120, 278-9). Items included modified for Towertown.

^j Mean standardized score on family traditionalism scale (see Laumann and Pappi, 1976: 74-9, 120, 278-9). Items included modified for Towertown.

membership of collective actors. With such information, it is possible to examine the internal homogeneity/heterogeneity of collective actors (cf. Laumann, 1973: 83-110). We would expect that the more socially and attitudinally homogenous the members of a collective actor, the more likely the formation of direct communication links among them, and the more cohesive and integrated the collective actor. Heterogeneously composed net-

works, on the other hand, might be more loosely interconnected. Coordination of effort in such networks is expected to be weaker and less effective than it would be in more homogeneously composed networks.

Inspection of Table 2 reveals patterned differences across collective actors with respect to several compositional characteristics. These observed differences among collective actors will be helpful in

the next section in interpreting their interrelationships based on overlapping memberships. Here, we would like to draw brief attention to certain systematic covariations among collective actors on these compositional attributes. To identify covariations of possible theoretical interest, we calculated the matrix of rank correlations for Table 2, separately for each community.

Rather than reporting all of these correlations in detail, we shall summarize those that appear to be of special interest in that they suggest salient characteristics of successful conflict groups.⁸ Recall, first, the results on size reported above. Next, we find that in both communities a moderate positive association between the proportion of a collective actor's membership which is active on the issue in question and its success ($r_s = .30$ in Altneustadt; $r_s = .51$ in Towertown). In Towertown we find that winning collective actors are somewhat more likely to include members drawn from the business or economic sector ($r_s = .49$); in Altneustadt, a similarly signed relationship is not as strong ($r_s = .32$). The collective actors in Altneustadt are better distinguished by the proportions of their membership drawn from the dominant political party—successful collective actors being much more likely to include such persons ($r_s = .84$). There is no association at all between these attributes in Towertown, confirming our general observations that formal political structures are of relatively little consequence in this American setting.

Turning next to the question of the influence resources possessed by winning collective actors, we first take note of the fact that a high proportion of members holding public authority is not strongly associated with success in either Towertown or Altneustadt. In fact, we find that the weak relationships which do appear are both negatively signed. In

Altneustadt, there is a low positive association ($r_s = .23$) between the proportion of members with reputations as public mobilizers and a collective actor's success; in Towertown, however, this is sharply reversed ($r_s = -.80$). These results suggest that influence processes in these communities take place largely in informal settings, where the influence resources treated as salient and legitimate by many authors are of relatively little consequence.

Finally, we shall briefly address the question of the extent to which the conflict groups in these communities are differentiated by ideological commitment. We find that, in Altneustadt, the successful collective actors are much more likely to espouse traditional values concerning family structure and practices ($r_s = .82$). This relationship is much weaker ($r_s = .09$) in Towertown. In the latter community, however, the winning collective actors include members who tend to reject socially egalitarian attitudes ($r_s = -.45$), an association that is somewhat weaker ($r_s = -.28$) in the German community. In general, however, the evidence suggests that the construction of collective actors depends much more on sharing an ideological orientation in Altneustadt than it does in Towertown. Thus, we have provided further support for an observation made elsewhere (Laumann et al., 1977) that the elite system in Towertown tends to be much more pragmatic and oriented to bargaining and negotiation by comparison with the more ideologically rooted conflict structure of Altneustadt's elite (cf. Laumann and Pappi, 1976: chap. 4, 6). We shall present further evidence for such a generalization in our examination of the oppositional structures of the two communities.

The Oppositional Structures of the Two Communities

In this section, we examine the overlapping memberships of collective actors in each community, in order to characterize its oppositional structure. To do this, we first constructed a binary matrix M , in which the element m_{ij} indicates the membership status of elite member i in

⁸ Two issues in Altneustadt, the industrial resettlement issue and the pop festival issue, were hypothetical. For these, the "successful" option was determined from the majority opinion of the elite as to which side, the proponents or the opponents, would be victorious (see Laumann and Pappi, 1976: 167-8n, 285-6).

collective actor j . We then formed the matrix product

$$S = M'M;$$

where s_{ij} gives the number of members shared by collective actors i and j and M' is the transpose of M (see Breiger, 1974).

It is useful to embed these patterns of overlapping memberships in a geometric space, so that we can examine them in relation to the four models of oppositional structure presented above. In doing this, we transformed the overlapping memberships, to assure that the geometric configurations would not be merely a reflection of the differential sizes of collective actors. Therefore, for each pair of collective actors, we cross tabulated dichotomous variables giving membership in each, and calculated the log-linear interaction parameter for that cross-tabulation. This defines the following proximity measure:

$$v_{ij} = \frac{1}{4} \log s_{ij} - \frac{1}{4} \log s_{i\bar{j}} \\ - \frac{1}{4} \log s_{\bar{i}j} + \frac{1}{4} \log s_{\bar{i}\bar{j}},$$

where v_{ij} is the proximity of collective actor i to collective actor j , s_{ij} is the number of members shared by collective actors i and j , $s_{i\bar{j}}$ is the number of persons who are members of collective actor i but not collective actor j , $s_{\bar{i}j}$ is the number of persons who are members of collective actor j but not collective actor i , and $s_{\bar{i}\bar{j}}$ is the number of persons who are members of neither collective actor. Note that different collective actors on the same issue are necessarily defined as having the lowest possible proximities to one another, since membership in collective actors is mutually exclusive within issues.⁹

The two matrices of proximities were then submitted to smallest space

analysis—I (SSA-1; Lingoes, 1973). Two-dimensional configurations of collective actors resulting from these analyses are presented in Figures 2 and 3 for Altneustadt and Towertown, respectively.

The first thing to note about the oppositional structure for Altneustadt is that three collective actors, A_p , C_p , and D_p , are unopposed. Secondly, observe that the opposition on the other two issues, the city hall and the pop festival, is fragmented into two collective actors. For these reasons we suggest that the oppositional structure in Altneustadt is a mixture of our theoretical models I and II. The two-dimensional configuration is necessary to accommodate the fragmentation.¹⁰

In Figure 2, the successful collective actors are arrayed to the right of the space, while unsuccessful collective actors are located toward its upper left corner. The axis sketched in the diagram follows the recurrent ideological split between the socially and economically liberal Social Democratic party (S.P.D.) group and the more conservative Christian Democratic Union (C.D.U.) supporters.

The second dimension of the space simply distinguishes between the two pairs of collective actors that share preferences on an issue but have no linkages to one another. This fragmentation is easily explained, given the social composition of these collective actors. The first pair of collective actors, B_{o1} and B_{o2} , share opposition to the construction of a new city hall. B_{o1} consists of S.P.D. supporters and fellow travellers recruited from the natural science research center who hold highly egalitarian views (see Table 2), while B_{o2} is a set of economically conservative C.D.U. businessmen with economic interests in the county rather than the city of Altneustadt, who objected to the building of an expensive city hall by their usual allies, the city-dominated C.D.U. personnel (B_p).

The two collective actors opposed to the pop festival, E_{o1} and E_{o2} , are both con-

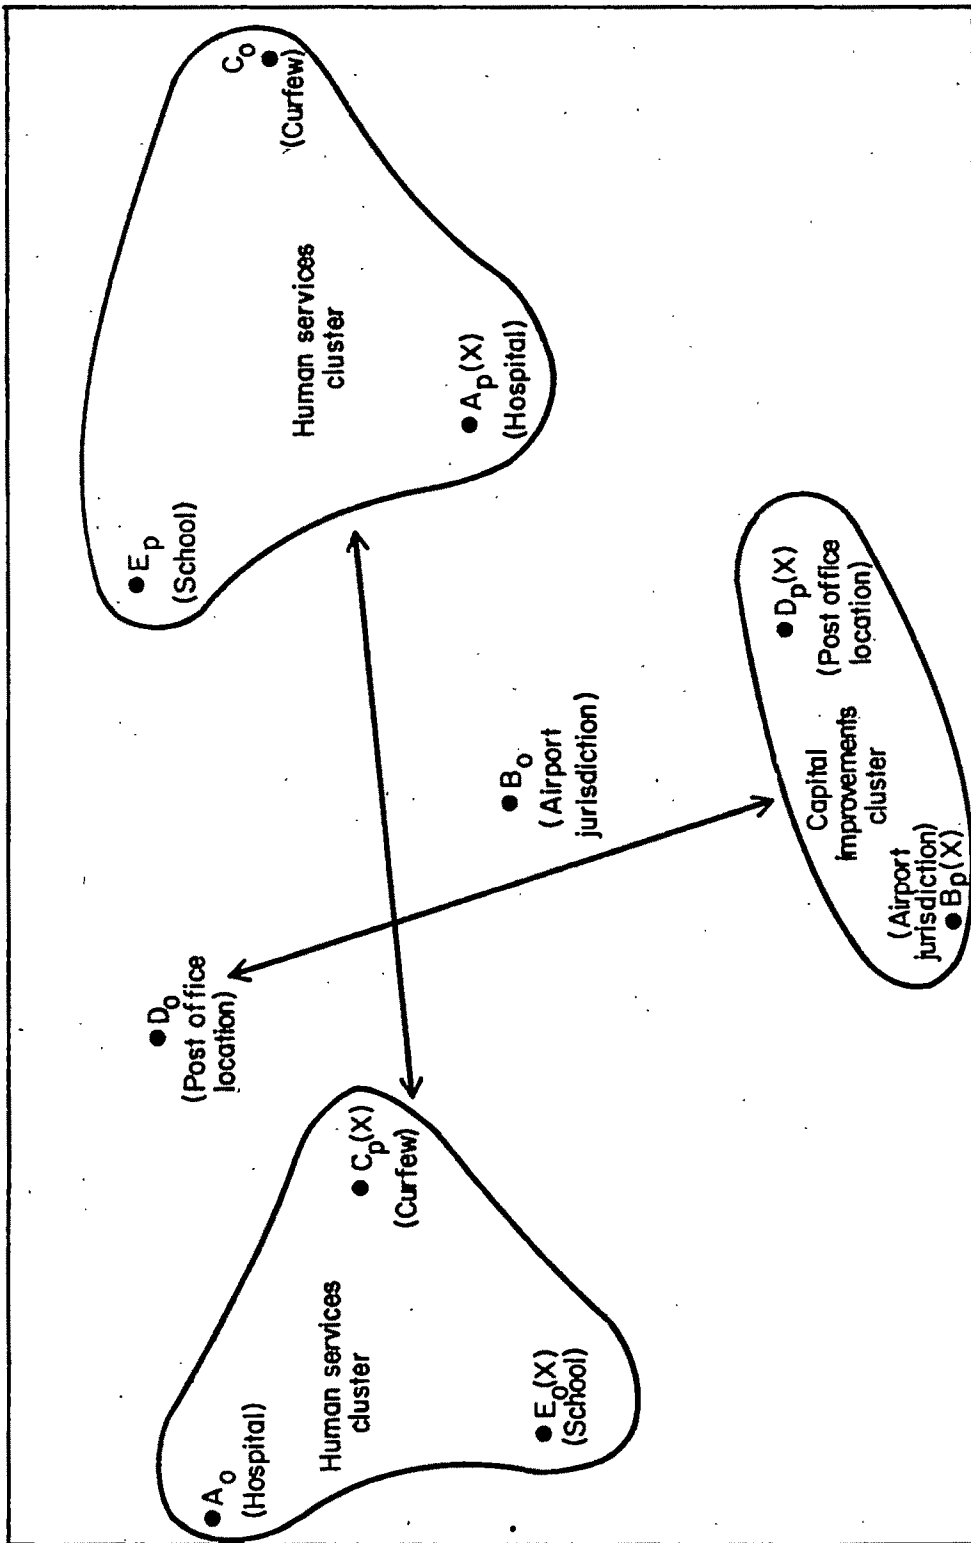

⁹ A small quantity (0.1) was added to each of the frequencies in the formula for v_{ij} to avoid taking logarithms of zero. This artificially creates differences in estimated proximities corresponding to zero overlaps in membership. Since the proximities corresponding to zero overlaps should indicate maximal distances between collective actors, and should be equivalent to one another, we equated the v_{ij} -scores corresponding to zero overlaps. This insures that they will be appropriately treated as ties by the multidimensional scaling algorithm used in our analysis.

¹⁰ The one-dimensional smallest space solution for Altneustadt had an unacceptably high coefficient of alienation of 0.24.

* Smallest-space analysis-1 (SSA-1; Lingoes, 1973) of proximities estimated from overlapping memberships. Coefficient of Alienation = 0.09. An (X) in parentheses indicates that a collective actor was successful.
Figure 2. Oppositional Structure in Altneustadt.*

* Smallest-space analysis-1 (SSA-1; Lingoes, 1973) of proximities estimated from overlapping memberships. Coefficient of Alienation = 0.14. An (X) in parentheses indicates that a collective actor was successful. Figure 3. Oppositional Structure in Towertown.*

servative in orientation. They are recruited, however, from quite disparate institutional sectors—the county-oriented industrial, agricultural, and land development sector, and the city-based commercial interests—and thus lacked opportunities to form communication channels. Note, however, that despite their fragmentation, it was the prevailing opinion in the elite that these groups would be successful in preventing the pop festival from occurring.¹¹

Note that two of the three unopposed collective actors, A_p , C_p , and D_p , are relatively central in Figure 2. This occurs because all are large and heterogeneous in composition. This insures that they have substantial overlap with all other collective actors in the system. D_p , however, is drawn toward the S.P.D. groups E_p and B_{oi} because the S.P.D. group initiated the proposal for a secular rather than a religiously based public middle school. At its onset the school controversy was quite bitter and divisive; it eventually attracted widespread support within the elite, though, drawing D_p toward the center of the oppositional structure in Altnestadt (see Laumann and Pappi [1976: 101–31; 163–72] for a more detailed treatment of these controversies and their partisans).

Examination of Figure 3 depicting the oppositional structure of Towertown's elite suggests that it is a good approximation to our theoretical model III, the multidimensional cleavage model with no coordinating center. First, note that the collective actors are arranged roughly in a circle. Observe also that successful collective actors are scattered fairly uniformly around the rim and are interspersed with losing collective actors. The rim formation further suggests that there is relatively little systematic overlap among winning collective actors. If such overlap had occurred, this would have drawn the successful collective actors toward the center of the space and cast the unsuccessful ones toward the periphery—thus forming the arrangement postulated in the polycentric bargaining structure of model IV. Finally, note the two nearly orthogonal dimensions, the

first contrasting collective actors concerned with the provision of human services, education, and health, and the regulation of conduct,¹² and the second ordering opposing collective actors concerned with major capital expenditures having implications for agricultural, industrial and residential land development.

The construction of a new regional (rather than city) hospital under private auspices raised questions both with regard to the commitment of substantial capital resources from the private and public sectors and with regard to the nature and character of the health services to be provided, especially the question of mental health facilities. Since this issue had both narrowly economic and broader social implications, it is interesting to note the intermediate location of A_p in Figure 3, between collective actors concerned with "purer" economic issues of airport jurisdiction and the location of a post office, and those concerned with the value-rooted issues of the curfew and the school.¹³

The only centrally located collective actor in Figures 3, B_o , was a loser, despite its size and heterogeneous composition. It included nearly the entire set of influentials in the city—thus its central location—who opposed the airport because of its costs to the city. This group, however, was unsuccessful because the authority to make the final binding decision was lodged in the county board of commissioners. The proximity of the winning C_p and the losing D_o arose from their overlapping membership of downtown businessmen who, on the one hand, op-

¹² The curfew issue is concerned with the regulation of conduct. In this issue, a curfew was imposed by the mayor in the aftermath of disturbances and destruction of property in the central business district by students protesting the bombing of Cambodia during the Vietnam War.

¹³ Members of E_p were primarily persons from the university community and their liberal allies. They opposed the closing of a progressively oriented school in the city system, that originally had been run by the university's School of Education as a laboratory and training facility. This school had been scheduled by the local Board of Education to be replaced by a conventional neighborhood school program.

¹¹ See fn. 8.

posed the location of the new post office in an urban renewal area inconvenient to the central business district and who also supported the mayor's imposition of a curfew after the "trashing" of the downtown business area.

Recall that there is little evidence to support the notion that the collective actors in Towertown are systematically differentiated with respect to basic social value orientations. This, in addition to the results shown in Figure 3, contributes to our characterization of Towertown's oppositional structure as a set of systematically shifting collective actors with no central coordinating core.

The images of oppositional structure that we have discussed here are in accord with the subjective perceptions of the influence structure reported by the elite members themselves. In Altneustadt, over 75% of the elite agrees that the oppositional structure is one in which there is persistent conflict between stable factions. By contrast, in Towertown perceptions are much less clear: a plurality of more than 45% of the elite members there describes the community structure as one of shifting coalitions, while over 40% characterizes it as a stable factional structure. This lack of clarity in Towertown is understandable, given the more complex structure of collective actors depicted in Figure 3.

Summary and Conclusion

We have proposed a new concept, that of a collective actor, that is to serve as the analytic unit in the study of oppositional structures in collective decision-making systems. After distinguishing this concept from others currently in use, we developed a set of spatial models describing the alternative forms of oppositional structure that have received attention in the literature. We then attempted to demonstrate the utility of our approach in a comparative analysis of two quite different community elite systems. Needless to say, much remains to be done in refining and elaborating the concept and the research strategies associated with it.

We will conclude by mentioning some implications of our work here for network

analyses of elite systems. We have not criticized the use of existing clustering techniques for the analysis of network data. What we have suggested is that in the study and depiction of conflict structures using such techniques, it is necessary to take explicit account of interests or preferences in addition to data on linkages between elite members. While preferences well may be associated with similarities in structural position within networks (Burt, 1978), the association is frequently weak enough to make it hazardous to characterize oppositional structures on the basis of network data alone. Equally importantly, one must not emphasize preferences to the exclusion of linkages; to do so is to ignore important questions concerning the social organization of conflict groups.

None of the above should be taken to imply that analyses of role structure (Burt, 1977; Breiger and Pattison, 1978) based on network data alone are not useful contributions. When investigators are specifically concerned with oppositional roles and structures, however, we think the approach offered here will prove preferable.

MANUSCRIPTS FOR THE ASA ROSE SOCIOLOGY SERIES

Manuscripts (100 to 300 typed pages) are solicited for publication in the *ASA Arnold and Caroline Rose Monograph Series*. The Series welcomes a variety of types of sociological work—qualitative or quantitative empirical studies, and theoretical or methodological treatises. An author should submit three copies of a manuscript for consideration to the Series Editor, Professor Robin M. Williams, Jr., Department of Sociology, Cornell University, Ithaca, New York 14853.

SMALL GROUPS AND CULTURE CREATION: THE IDIOCULTURE OF LITTLE LEAGUE BASEBALL TEAMS*

GARY ALAN FINE

University of Minnesota

American Sociological Review 1979, Vol. 44 (October):733-745

Following interactionist theory, this study argues that cultural creation and usage can be examined by conceptualizing cultural forms as originating in a small-group context. Those cultural elements which characterize an interacting group are termed the *idioculture* of the group. This approach focuses on the content of small-group interaction, and suggests that the meanings of cultural items in a small group must be considered in order to comprehend their continued existence as communication. Five characteristics of cultural items affect which items will become part of a group culture. Cultural forms may be created and continue to be utilized in situations if they are *known* to members of the interacting group, *usable* in the course of group interaction, *functional* in supporting group goals and individual needs, *appropriate* in supporting the status hierarchy of the group, and *triggered* by events which occur in group interaction. These elements have impact only through the interpretations of group members of their situations. Support for this approach is drawn from a participant observation study of Little League baseball teams.

The concept of culture generally has not proven useful as a significant variable in sociology because of difficulties associated with specifying its content and the population serving as its referent. One speaks glibly of the culture of a particular group with the expectation that one's audience will have a common-sense understanding of what is meant. Because of the difficulties and ambiguities involved in the use of the term *culture* (Geertz, 1973:89), it virtually has been disregarded in recent sociological writing as a major theoretical variable.

The term refers to a central feature of human societies, and because of its sociological relevance, a reconceptualization of the culture concept is desirable. However, in order to avoid treating culture as an amorphous, indescribable mist which swirls around society members, it is

necessary to ground the term in interaction. Such specification can avoid the lack of common meaning often involved in studies of national cultures or subcultures. Blumer (1969) has argued that meaning derives from interaction, and culture, a set of shared understandings, is clearly implicated in Blumer's premise. While culture is defined, created, and transmitted through interaction, it is not interaction itself, but the content, meanings, and topics of interaction. In Herskovits's (1948:625) definition:

though a culture may be treated by the student as capable of objective description, in the final analysis it comprises the things that people have, the things they do, and what they think.

Sociologists and anthropologists who have examined culture have found specifying the cultural patterns of an entire society to be an insurmountable task. While the attempts have been noble, the size of the undertaking has produced disappointing results for the goal of understanding the dynamics of cultural creation and tradition. If we take Blumer's premise seriously, it may be more suitable to begin our examination with interaction, and therefore to consider culture creation as an outcome of this interaction (e.g., Hare

This article has benefited enormously from the critical reading of many, especially Robert Freed Bafes, Pat Lauderdale, Sherry Kleinman, Harold Finestone, and Jim Thomas. The views expressed, however, represent those of the author. Part of the research was supported by National Science Foundation Grant No. SOC75-13094. Data from the Maple Bluff site were collected by Harold Pontiff.

et al., 1965:v). The prototype of these interacting units is the small group, and the prevalence of groups in society suggests that it may be useful to conceive of culture as being part of the communication system of these interacting units (Spector, 1973). Despite the focus on the group, we recognize that this does not imply that shared understandings which transcend interactive networks do not exist; however, models are necessary to indicate how information diffuses from the originating group (see Fine and Kleinman, 1979). Although cultural elements can transcend the boundaries of interacting groups, it frequently occurs that cultural elements are experienced within the context of the small group. Thus, one may argue that most culture elements are experienced as part of a communication system of a small group even though they may be known widely.¹ The experience of knowing and using culture is inevitably tied to situational contexts of group life. To understand the dynamics of cultural creation and cultural change, we must analyze this knowledge within the context of its mode of transmission.

In focusing on the interacting unit, I argue that every group has to some extent a culture of its own, which I shall term its *idioculture*.² Idioculture consists of a system of knowledge, beliefs, behaviors, and customs shared by members of an interacting group to which members can refer and employ as the basis of further interaction. Members recognize that they share experiences in common and these

experiences can be referred to with the expectation that they will be understood by other members, and further can be employed to construct a social reality. The term, stressing the localized nature of culture, implies that it need not be part of a demographically distinct subgroup, but rather that it is a particularistic development of any group in the society.

While the implications of conceiving of small groups as having cultures have not been considered adequately, some researchers have indicated the usefulness of this construct. Hollingshead (1939:816) in his discussion of behavior systems maintained that:

Persons in more or less continuous association evolve behavior traits and cultural mechanisms which are unique to the group and differ in some way from those of other groups and from the larger socio-cultural complex. That is, every continuing social group develops a variant culture and a body of social relations peculiar and common to its members.

Lee (1954) and Gordon (1964) both suggest that the concept of a group culture fills a void in sociological conceptions of culture. Despite anthropological and folkloristic ethnographies (Leemon, 1972; Adams, 1971; Dundes and Fallasi, 1975) and experimental manipulations of laboratory groups (Rose and Felton, 1955; Jacobs and Campbell, 1961; Weick and Gilfillan, 1971; MacNeil and Sherif, 1976), little attention has been given to the usefulness of this concept, and how social constraints influence the creation and continued usage of cultural items in small groups.

My goal in this paper is simple. After briefly suggesting several theoretical rationales for the idioculture construct, I shall examine several perceived characteristics of cultural items which affect their creation and usage, and, thus, the development of idiocultures within a set of small groups. Hopefully this analysis, having grounded the cultural creation process in interaction, eventually will allow for a specification of the dynamics involved in the social construction of cultural elements in larger groupings and societies.

¹ Cultural elements disseminated by the mass media (television, radio) or in crowd settings (rock concerts, rallies, sports events) are exceptions. However, even in these isolated or mass settings Fine (1977) suggests that audiences are not composed of discrete individuals, but of a collection of small groups. These small groups help to structure the meaning of the event for individuals in attendance. Printed matter generally is notable for the noninteractional acquisition of cultural knowledge—although even here the material is often discussed with others.

² *Idio* derives from *idios*, the Greek root for *own* (not *ideo*). It was felt necessary to coin a new term because the most logical phrase, that of *group culture*, has been used previously with several quite different meanings (Thelan, 1954; Rossel, 1976; McFeat, 1974).

LITTLE LEAGUE IDIOCULTURES

In order to explicate how an idioculture develops, it is necessary to base the discussion on empirical observations. While the examination of any set of continuing small groups could provide the material for this analysis, the data discussed in this paper derive from three years of participant observation research conducted with Little League³ baseball teams in five communities in New England and Minnesota. Little League baseball teams were chosen for observation because they combine the two major elements of group life: task orientation (winning games) and socioemotional orientation (peer friendship).⁴ In addition, because Little League is seasonal, the creation, development, and dissolution of the team culture could be observed. While some traditions continue from year to year, as approximately one-half a team's personnel returns, each year essentially represents the creation of a new idioculture.

The teams examined consisted of 12 to 15 preadolescents, coached by one to three adults. Over the course of a three-month season, teams play 14 to 21 games and, including practice time, spend about ten hours a week together. During the seasons the author (and, in one league, a research assistant) interacted with players

and coaches (Fine and Glassner, 1979), although the observer had no formal role, such as coach or umpire. Within each league two teams were observed in detail, and during practices and games the observer remained with the team in the dug-out or on the field. The five leagues examined were: (1) Beanville,⁵ an upper middle-class professional suburb of Boston, Massachusetts; (2) Hopewell, an exurban township outside the Providence, Rhode Island metropolitan area—consisting of small towns, beach-front land, farms and a campus of the state university; (3) Bolton Park, an upper middle-class professional suburb of Saint Paul, Minnesota, similar to Beanville except for geographical location; (4) Sanford Heights, a middle- to lower middle-class suburb of Minneapolis, consisting primarily of developers' tract homes; and (5) Maple Bluff, an upper middle-class neighborhood within the city limits of Saint Paul, Minnesota. The latter teams were examined by a research assistant. In Beanville participant observation was conducted during two seasons, while in the other sites observation was confined to a single season.

RATIONALE FOR THE IDIOCULTURE CONSTRUCT

Because discussions of culture have not been grounded in observation of interaction or conceived of in terms of behavioral dynamics and needs of groups, culture has not been represented adequately. By recognizing that groups develop a culture of their own, some of the sterility of much current small-group research can be avoided. Five arguments are proposed here for the utility of the construct of idioculture in sociological research.

1. *Specificity of Cultures*

Since small groups are observable and are capable of being questioned, culture need not remain the amorphous phenomenon which it tends to be in social an-

³ The Little League organization was established in 1939 for the purpose of allowing boys to play organized baseball under the supervision of qualified adults. The organization has grown enormously since then to the point where it now has over 600,000 players between the ages of nine and 12, and about 5,000 leagues. As a result of court suits from equal rights groups, the League changed its policy in 1974 to admit both boys and girls into its programs. However, the ten teams examined in-depth in this project consisted only of boys.

⁴ While the decision to use Little League baseball teams to exemplify cultural production may appear somewhat frivolous, such groups are as important to their participants as most adult groups. For the months that the Little League season is in progress, baseball becomes a central preoccupation of these boys (Stone, 1978). Further it is the problem that one studies which determines the significance of the work, not the "substantive" concern, in this case Little League baseball. If these groups are comparable to other groups in their process of cultural production (as I claim), they are a legitimate subject for study. I am attempting to generalize to all groups, not simply preadolescent congeries.

⁵ All names included in the report of the Little League research are pseudonyms.

thropology and macrosociology. The relatively limited extent of the particularistic aspects of small-group culture lends itself to examination by the participant observer, and thus idiocultures can be specified by the researcher to a much greater extent than is true for either societal cultures or subcultures. Within our Little League study it is possible to compose a relatively complete description of the culture of a team, although the depiction of a culture of a small group of small boys is a rather extensive undertaking (Fine, n.d.). Such a compilation will include the particular team rules developed by the group of boys and their coaches, the regular joking topics, nicknames, and modes of appropriate behavior adopted by the boys. A comprehensive attempt to compile preadolescent culture is an impossible task, although several useful partial collections have been published (e.g., Opie and Opie, 1959).

2. Comparative Analysis of Groups

The concept of idioculture allows for the development of a cultural anthropology of small groups (McFeat, 1974). Social scientists typically have little understanding of how closely related groups differ from each other. These groups may appear to have common goals (winning baseball games), comparable memberships (chosen by means of a player draft in which all adult coaches take turns selecting players), and similar environments (playing and practicing in the same locations), yet groups develop unique cultures and different styles of behavior. Here, again, the examination of differences among groups requires considerable space, more than is possible in this article. However, it is clear that the cultures that teams develop are a result of social and environmental contingencies, combined with the social definitions which emerge in group interaction. Once the idioculture is developed (a process occurring from the beginning moments of the group), it shapes future actions and collective meanings. By comparing groups in terms of their experiences and shared meanings

as influencing their culture, one is able to explicate the process of cultural differentiation—a process Fischer (1968) has termed *microethnography*. In our Little League research early victory or defeat (a social contingency) and the definition of that outcome have a considerable effect on structuring the team culture. Teams that perceive themselves as successful typically develop a more robust culture of baseball-related items than the culture of early losers.

3. Cultural Creation and Diffusion in Societies and Subsocieties

Understanding the dynamics of the creation of an idioculture may have significant implications for understanding cultural creation in larger social units. In observing a small group one can pinpoint precisely and with confidence the circumstances under which an item of culture was created. This cultural creation process may be similar to that for cultural products which reach a wider audience. Many cultural products are created in group situations (e.g., scriptwriters' conferences, theatre ensembles or scientific research groups) (Fine, 1977). Informal cultural products, such as jokes, slang, or superstitions, can develop in the course of natural interaction in a group, and subsequently may "catch on," spread beyond the boundaries of the group to which it originally belonged, and become part of a culture or subculture (Fine and Kleinman, 1979). Such mass diffusion does not occur very frequently, and our research does not allow us to cite any example in which a cultural object created by one of the observed teams entered into the national preadolescent subculture, but on several occasions cultural traditions crossed team lines. One team in Bolton Park, for example, started standing on the dugout bench and cheering. This practice subsequently was adopted by two of the other six teams, through acceptance by the high status players on those teams, and the diffusion rapidly spread to their teammates. Such examples of diffusion suggest general processes of cultural transmission (e.g., the two-step flow of

communication) (Katz and Lazarsfeld, 1955).

4. *Groups As Cultural Units*

The idioculture construct indicates that groups do not exist in a content-free context, but are continuously engaged in the construction of a social reality, a history (McBride, 1975), and a sense of meaning (Berger and Luckmann, 1967). Small-group research typically portrays groups as data points, and examines group dynamics divorced from the content of talk or action. Following interactionist theory, we assume that cultural content derives its shared social meaning through interaction, rather than through an a priori assignment of meaning. Groups negotiate meanings, and this ongoing negotiation structures the culture of groups. The content of talk and behavior is thus central to the comprehension of group dynamics, and this understanding can occur only through a contextual examination of culture. The nicknames of Little Leaguers—Big Rides, Shrimppo, Thunderfoot, Train, or Maniac—imply that shared meanings of players exist and the replacement of nicknames over time suggests that these meanings are not necessarily static. Without a consideration of meaning, behavior is “meaningless”—a point experimental examinations of small groups ignore or downplay.

5. *Culture As Mediation between Environment and Action*

Idioculture is proposed as a mediating element between constraints external to the group and the behavior of the group in dealing with these constraints. It is the process by which collective decisions are selected, and thus permits an understanding of how a group increases its sense of “groupness,” cohesion, and commitment. Further, as Berger and Luckmann (1967:87) suggest, sub-universes of meaning (idiocultures) provide for the differentiation of group members from outsiders. Differences in behavioral response to social stimuli and

social integration have been shown convincingly to relate to the cultural values of small communities (Vogt and O’Dea, 1953; Rogers and Gardner, 1969; DuWors, 1952). The culture of a group provides a set of behavioral options for the group to choose after the meaning of an external event has been determined. Thus, in this Little League research, teams responded idiosyncratically to potential victory (by special cheers) and defeat (by personalized insults). The team achieves consensus on whether the game is close, is being lost or won; then members choose from the group’s repertoire of cultural options available given a situational definition.

Each of these five explanations deserves a full explication and, although this article only attempts to provide for an understanding of factors influencing the social production of idiocultural elements, a return to the above arguments in future reports is necessary.

THE SOCIAL PRODUCTION OF IDIOCULTURE

At the inception of any group, an idioculture does not exist; however, the formation of a culture may occur from the opening moments of group interaction. When individuals meet, they begin to construct a culture by asking for names and other biographical points which can be referred to subsequently (Davis, 1973). Eventually idioculture becomes self-generating, and direct solicitation and reciprocal inquisition are no longer necessary for social solidarity. Over time, rules are established, opinions expressed, information exchanged, and members experience events together. Sherif and Sherif (1953:236–7) suggest that:

When individuals having no established relationships are brought together in a group situation to interact in group activities with common goals, they produce a group structure. . . . This group structure implies positive in-group identifications and common attitudes and tends, in time, to generate by-products or norms peculiar to the groups, such as nicknames, catchwords, ways of doing things, etc.

To be sure, not every element of a group's conversation or behavior will be part of the idioculture. Idioculture is augmented if an experience occurs or a piece of information is transmitted *within* the group (i.e., in the presence of more than one group member) and is perceived as an event or statement which can be referenced legitimately and meaningfully (see Garfinkel, 1967:38-41)—i.e., the occurrence is worthy of retrospective notice. Thus, in Little League, a routine hit or catch, being "taken for granted," usually will not make an impact on the group's idioculture, but may become notable if the situational constraints give the event a significance beyond its expected lack of impact (e.g., a catch by a poor outfielder at a crucial point in a game—an event which did produce a nickname in one Little League scenario).

The specific elements of an idioculture are not generated randomly through chance statements and events, but are accessible to sociological analysis. However, it would be inaccurate to suggest that the cultural elements of a group are inevitably produced by external determinants over which members have no control. Members construct meanings given a set of social constraints which are perceived as affecting the boundaries of permissible behavior. While the content of cultural elements needs to satisfy five analytical criteria to become incorporated into an idioculture, these five criteria are not external stimuli which inevitably shape the behavior of individuals or groups. Rather, these are components of the sense-making systems of individuals; the specific implications of these criteria are negotiated in group interaction. These processes essentially operate as filters (Siman, 1977), which constrain cultural options. They provide strictures within which freedom of selection operates.

The five filtering elements are proposed to explain the selection and continued salience of any given item in a group's idioculture—that the item be perceived as Known, Usable, Functional, and Appropriate in terms of the group's status system, and Triggered by some experienced event. These factors can be schematized

roughly in an ordered relationship by a Venn diagram according to the number of *potential* items which meet each criteria: $K > U > F > A > T$. The manner in which each of these filters will be interpreted is a situational achievement for members, and although I shall take for granted their operation in this discussion, I recognize that the interpretation of each of them is grounded in their own set of situational negotiations.

Known culture. The first constraint on whether a potential culture element will become part of the group idioculture is that the item or components of the item be known previously by at least one member of the group. This pool of background information I shall term the *known culture* of the group.

This perspective is congruent with Becker and Geer's (1960) argument that the manifest culture of a group will be derived from the latent cultures of members. While the culture content emerges from group interaction, latent culture or the recall of prior knowledge will affect the form of these culture elements, although not the specific content. Culture content is synthesized from remembrances of past experiences. Since members have access to other idiocultures (or latent cultures) through previous or concurrent memberships, the range of potentially known information may be extensive.

Among Sanford Heights teams, a ball which was hit foul over the backstop was known as a "Polish Home Run." Such a cultural item would have been meaningless had it not been for latent cultural items—what a home run is, and the symbolic opposition of hitting a ball straight over the outfield fence and hitting it backward over the backstop. In other words, hitting the ball over either *end* of the field was a home run (and this was not said of balls which curved outside a foul line). The existence of the item also required a knowledge of social stereotypes—that "Polish" is an ethnic slur—implying backwardness or incompetence. Without this cultural knowledge such an identification of this type of foul ball would not have become a part of the culture of these preadolescents. Likewise,

referring to other players on the basis of their uniform color as a "green bean" or "Chiquita," as was done in Hopewell, suggests that cultural elements are dependent upon prior knowledge derived from external sources.

Creativity poses no particular problems for this perspective since created items are not developed *de novo*; rather, they are novel combinations of previously familiar elements (e.g., Hebb, 1974). These combinations may be given meanings different from that of any constitutive element by the members of the group. Thus, players on the Maple Bluff White Sox developed a dress code which was loosely modeled on observation of major leaguers, although not identical to it. Before one practice in Sanford Heights several players were hanging on the backstop at the practice field while one of their teammates shook the fence as hard as possible, an activity he termed the *Chinese pain shake*, a term apparently created spontaneously. While the term may never have been uttered before, its antecedents exist in that speaker's latent culture: notably the association of Chinese with torture (e.g., the Chinese water torture), and the earthquakes which had affected China during this period and to which this activity was similar. Thus, the creation of this cultural item, although seemingly an idiosyncratic construction, can be interpreted in terms of previous knowledge. The term for that behavior "makes sense" in terms of the web of meanings accessible to those individuals.

The larger the percentage of boys who share a latent cultural element (e.g., the behavior of certain professional baseball players in wearing their hats or socks in a particular style), the more likely will this knowledge or some transformation of it come to characterize the group. This unstated shared knowledge allows newly "created" cultural items to be more readily meaningful for the group.

Usable culture. The second criterion for inclusion in a group's idioculture is that a potential item be perceived as part of the members' *usable culture*—that is, mentionable in the context of group interaction. Some elements of the latent or

known culture, although shared by members of a group, may not be shared publicly because of sacred or taboo implications.

The usability of a cultural element is not a result of absolute criteria, but of the social meanings supplied by the group members. Members' personalities, religion, political ideology, or morality may influence the situational viability for a cultural item. Thus, in Bolton Park one star player objected strongly to another player's reference to the "fucking umps"; another player on that team chastised a teammate for uttering the epithet "Jesus Christ" and taking the Lord's name in vain. On other teams, however, such usage was legitimate and was not sanctioned. Observation suggests that teams do have different moral standards for propriety; this is due to their adult and child personnel, and the extent to which these personnel are willing to express their beliefs to shape public behavior.

In Beanville, one of the two teams examined placed a heavier emphasis on religion than did the other, although both teams were largely Catholic. Possibly because of the players or as a reification of the team name, the Angels indicated a greater interest in religion than did the Rangers. Members of the Angels inquired of each other why they missed church. The Rangers never publicly mentioned church, but on several occasions players did joke about abortions. While only a weak inference exists that similar jokes could not have occurred among the Angels, the presence of such jokes seems unlikely and inappropriate. "Dirty" or sexual jokes were only spread among groups of Rangers (outside the earshot of their coach), and not in my observation among the Angels.

Similarly, on one team in Hopewell, racial epithets were common; one player made reference to blacks as "jungle bunnies," while another commented "all the people who live around me are niggers," and a third termed a Puerto Rican adolescent "half nigger and half white." While many of the boys in the League were undoubtedly aware of these terms, only on this one team were they spoken with any

regularity, and as part of the normative order of the team. It is difficult to pinpoint why these comments were usable here and not elsewhere, but two years previously this team had a black manager who apparently was not well-liked, and this may have accounted for the public expression of racial resentment after he left. This is compounded by the situation that the two adults who coached this team did not appear to be greatly upset when this language was used. For example, we find this disquieting colloquy:

(A black boy pitching for the opposing team has just hit one of their batters)

Justin: "Come on, you nigger."

Coach: "Don't be stupid."

Justin: "That's what he is."

Assistant Coach: "You'll get thrown out of the game."

Justin: "I don't mind if he calls me whitey."
(Field notes)

The issue here is the reaction of the coaches in establishing a definition of usability. In this situation, and others, these adults see racial abuse as a *strategic* problem. Boys should not use these terms because other adults will sanction them, or because (on other occasions) it was said the targets may attack the speaker. The reactions of the adults, while not encouraging these comments, do not make them unusable, and they remained a central part of the team's culture throughout the summer.

Tied to usability is situational appropriateness. Norms for prescribed and proscribed behavior tend to be contextually bounded. An item of culture may be appropriate only in certain circumstances, such as when the coach is absent. Typically, when group members are in the presence of outsiders the expressible elements of the team's idioculture are curtailed. This is evident in regard to preadolescents who refrain from telling "dirty" jokes in the presence of adults or strangers. Jokes comparing aborted babies to ripe, red tomatoes among the Beanville Rangers were limited to situations in which adults, other than the author, were not present. Likewise, one boy on the Sanford Heights Dodgers was

called "Mousey" by his affectionate mother. This nickname was used by peers in his absence, since he was a high status team member and it was a nickname he particularly disliked. This dislike only made the nickname more precious for his teammates.

Functional culture. A third factor influencing the likelihood of an item being incorporated into a group's idioculture is its perceived congruence with the goals and needs of some or all group members, and whether it is defined as facilitating the survival and successful operation of the group as a unit (Pellegrin, 1953). Items which are consistent with these ends are termed the *functional culture* of the group. Thus, potential cultural elements which are known and usable by members may not become part of the group's idioculture if not recognized as supportive of the needs of the group or its members. In some cases of cultural innovation, especially in regard to competing cultural elements related to task goals, a cultural process metaphorically akin to natural selection may operate.

Some interactionists argue that culture develops as a response to shared problems (Becker and Geer, 1960; Hughes et al., 1968; Spector, 1973); they claim that group culture is functional, and that much of culture production is directly related to group problem solving. This proposition is supported by an examination of group culture in a laboratory setting which indicates that problem-solving strategies that continue across time are those which have been most effective (Weick and Gilfillan, 1971).

Among Little League baseball teams, the rules and restrictions which team members enforce indicate the functional properties of group culture. The Beanville Rangers originated and enforced an operating procedure that the team would take batting practice (a desirable activity for the players) in the order that players arrived. This procedure encouraged promptness and, on occasion, the entire Ranger team arrived at the field before any members of the opposing team. The Rangers particularly were characterized by team spirit and friendships, as players knew each other informally through this

pregame activity; it served as a mechanism for minimizing arguments about the batting practice order. The preadolescents, rather than the coaches, structured the team's behavior, and the procedure strengthened the position of the team's preadolescent leader who lived a block from the field and always arrived early. Prior to the establishment of this procedure, batting order was determined haphazardly—mostly by whomever was most insistent at the moment, rather than by a systematic ordering procedure by the coach. It was because the ordering of batting practice had been problematic for the Rangers that such a rule was functional as a problem-solving mechanism.

A Hopewell team prohibited chewing gum on the playing field because one of their players had almost choked on a piece of gum after he ran into another outfielder when attempting to catch an unexpected fly ball. Other teams in the league did not have a similar rule, because the issue was never salient. For an item of culture to be overtly functional to a group, the group must define itself, either implicitly or explicitly, as having a problem, and then the cultural item may be proposed as a solution to the problem.

Some cultural items do not directly address problems in a group, but still may be said to be functional in that they achieve group goals such as entertainment or social solidarity. While they may not be proposed in response to interactional difficulties, these idiocultural items facilitate group functioning. The creation of cultural prescriptions and proscriptions is tied directly to their functional character. The origins of nonovertly functional culture items may not be related directly to the needs of the group, but their continued usage is.

Appropriate culture. Some potential elements of a group's culture, while functional for satisfying group goals or personal needs, do not occur or continue because they undermine the group's social structure in not supporting the interpersonal network and power relations in the group. Those potential cultural elements which are consistent with the patterns of interaction of the group are the *appropriate culture* of the group. A cultural item

which expresses hostility toward a well-liked or legitimately powerful individual may be known, usable, and even functional (in that hostility may need to be expressed), yet may be inappropriate unless the group structure is altered (see Hollander, 1958).

This becomes clear in the case of nicknames. Many nicknames are evaluative in context, and a nickname must fit the target's defined status in the group. During the first year of observation of the Beanville Rangers, one team member, Tom, acquired the nickname "Maniac," based upon a linguistic play on his last name, and on his physical awkwardness on the baseball diamond. That year he was an eleven-year-old substitute outfielder. When the team members were asked to name their three best friends on the team during the middle of the season, Tom was named only by one of the 12 other boys answering the sociometric questionnaire (with 15 players on the team). According to sociometric ranking and formal status, Tom is a low-status team member. The question formulated that season was: What would happen the following year when he was 12 years of age, and presumably would be one of the better players on the team? The following year, Tom started most of the Rangers' games at third base, was one of the best batters on the team, and was located in the middle of the team's status hierarchy. In sociometric ratings both at the beginning and the end of the season, Tom was named by four of the 14 other players as one of their three best friends on the team. His previous nickname, "Maniac," was no longer in circulation, although Tom and other team members recalled its presence during the previous year. Tom's new nickname was "Main Eye," again a play on the boy's last name, though with dramatically different symbolic connotations.

A similar example occurred the following year in Sanford Heights. One of the eleven year olds on the Giants was known as a particularly poor baseball player, having gone hitless in his previous year in the league. As a function of his weak baseball skills and his somewhat isolated position on the team, he was called

"Smell-ton," again a play on a surname. During the first week of the season, much to everyone's surprise—his own included—he hit a Grand Slam home run. His nickname "Smell-ton" was forgotten and, for the rest of the season, his teammates called him Jim. Status can be usefully conceived of as constraining the creation of nicknames, although the labeling effect of nicknames and other culturally identifying information on group position cannot be denied. Nicknames are not the only cultural items subject to status considerations; pranks and practical jokes may only be performed on low status members, and rules may be constructed so that they support the prerogatives of the older players—such as determining who should coach on the bases (high status boys) or who should go to the refreshment stand for water (isolates).

In addition to being affected by status inappropriateness, acceptance of a cultural item may be contingent on the nature of sponsorship. Potential cultural items are more likely to be accepted into a group's idioculture when proposed by a high status member (Sherif and Sherif, 1953:252). This clearly applies when the coach proposes some cultural element; while these are not invariably accepted by his preadolescent charges, they do stand a comparatively greater likelihood of acceptance. Thus, in Hopewell, one set of coaches suggested that before a game their team should form a circle, that team members place their hands in the middle of the circle and, when the coach said "Let's go," that players should buoyantly raise their arms in unison. This ritual characterized the team throughout the season. Another coach in Maple Bluff ritually asked his team what three things they needed to win, and they vigorously responded, "Hustle, pride and class;" a third coach in Beanville would refer to a weak hit as something which his grandmother could hit better than, and so the comic image of this middle-aged man's grandmother entered the team's culture.

High status players, like coaches, find their personal status accorded the traditions they wish to establish. Several members of the Beanville Rangers got

wiffles (short haircuts) after Wiley, the second most popular boy on the team, got one and was proud of it. This fad continued (with one or two boys newly shaved each day) until Rich, the most popular boy on the team, publicly claimed that he thought the haircut looked stupid, although he deliberately excluded Wiley from this evaluation, saying that he looked good. After Rich's announcement, only one low status boy had his hair cut in that fashion, and the team, highly critical of his tonsorial style, said it looked horrible and, further, it was not a *real* wiffle. Similar sociometric processes affected clothing conformity, such as wearing wristbands or sneakers at games, and wearing shorts or removing one's shirt at practice.

Triggering event. The range of *potential* cultural items which qualify as known, usable, functional, and appropriate is extensive, and some interactional mechanism (or filter) is necessary to account for which items enter the group's cultural repertoire. The concept of a *triggering event* is postulated as an explanatory device to determine selection. Some bit of interaction will provide a "spark" which produces the specific content of the idioculture. This event can consist of any action or statement which produces a response in the group, similar to Smelser's (1962) concept of a precipitating factor for collective behavior. A member's new haircut may be sufficient to spawn a new nickname ("Kojak," "Buzz Conroy," "Peach Fuzz"). A miscue may provide the impetus for a joking sequence that remains part of group lore. A threat to the group may produce a legend, new norm, or a prescription for group action.

While any triggering event may theoretically produce idioculture, some events recur and, in those cases, items of idioculture are particularly likely to be produced and, once produced, will more likely be relevant to the group as they are repeatedly functional and appropriate. Thus, the superior batting of one Beanville youngster led to him being called "Superstar," and the opposite talent of a boy in Bolton Park produced his nickname: "Strike Out King." These nicknames are sociometrically appropri-

ate, as well as being frequently triggered, because of the differential athletic achievements of these two youngsters.

In addition, triggers which are notable or unusual are especially likely to produce idioculture.⁶ Support for this assertion is provided by Gmelch (1971) in an examination of baseball superstitions in the professional leagues; he discovered that rituals emanated from particularly good performances, while behavioral taboos resulted from notably poor performances. One Bolton Park coach's old Impala was called a "Cadillac" after a foul ball nearly hit it in practice and he jokingly told them not to hit his Cadillac. The term caught on, and the rusty car was called a "Cadillac" from that point on—the notable event of a wayward foul ball structured the culture creation of the team. As Gmelch notes, notable events also effect taboos. One Hopewell coach brought his team red, white, and blue wristbands on opening day, in order to give the team some sense of unity and specialness. However, the team, which was expected to win the championship that year, lost its first game by the embarrassing score of 12–3. After the game, the players decided that the wristbands were unlucky and from that day no member of the team wore a wristband, and the team eventually won the league championship.

Triggering events and their effects are difficult to predict in advance in natural settings, as they are emergent from social interaction. However, in an experimental setting, triggering events can be systematically arranged by the researcher and their effects upon the content of group culture examined. This constitutes a valuable direction for research in this area.

Summary. Five elements—the known culture, the usable culture, the functional culture, the appropriate culture, and the triggering event—influence the specific

content of a group's idioculture. Different configurations of these five factors suggest how groups come to differ in their culture, and why specific forms appear and remain in particular groups. To this point, cultural forms have been analyzed using a single characteristic; in order to indicate the combined impact of all five we shall examine the creation and usage of one particular cultural item considering all factors.

During the middle of the season, the Beanville Rangers created and enforced a rule that no player could eat ice cream while sitting on the bench during a game. This rule was triggered by a combination of circumstances: it occurred in the context of a game in which the Rangers, by that time accustomed to victory, were being beaten. On the bench, one of the nonplaying low status players was eating an ice cream cone. This situation triggered the decision by the high status, older⁷ players (not the coach) that ice cream could not be eaten on the bench (although gum could be chewed). The rule was known in that it was compatible with the policy and perspectives of professional sports teams. It was usable in that it did not deal with any tabooed or threatening areas of children's culture, and it is comparable to the rules that children frequently make in interaction with each other (Piaget, 1932; Cooley, 1902). The rule was functional in relieving the frustration that the older players felt during that game, and in tending to get the attention of the younger members on the team. Further, the presence of a set of rules or rituals may create a sense of group cohesion (Cartwright and Zander, 1953) and satisfaction (Borgatta and Bales, 1953). Finally, it was appropriate in that it was propounded by the high status members to control the low status members. Later in the season an older, high status player did eat ice cream on the bench, and was not

⁶ Kelly (1967) has noted that distinctiveness or uniqueness tends to create attributions focusing on the characteristics or properties of the distinctive other. In the case of persons, these attributions generally refer to dispositions. Kelly also notes that consistency of behavior over time or modality (as in the case of recurring triggering events) produces attributions based on the characteristics of the other.

⁷ Age (in years) and the percentage of the total number of sociometric choices received (with the opportunity for each boy to name three team members as friends) correlated $+ .48$ ($p < .05$) at the beginning of this season, $+ .59$ ($p < .02$) in the middle of the season, and $+ .61$ ($p = .01$) at the end of the season.

criticized by other team members, although the rules remained for other team members.

CONCLUSION

Sociologists have had considerable difficulty in analyzing the position of culture in society because of a general unwillingness to examine culture in its behavioral context. Culture, like all aspects of social life, is situationally grounded and, thus, sociologists should bracket grand theorizing about culture in favor of examining it in situ. For both theoretical and methodological reasons, an examination on the level of the small group seems desirable. Small groups can be examined adequately, and they represent locations where much culture, subsequently spread to larger social units, has its origin. This procedure, in addition to increasing understanding about the social role of culture itself, also has the potential for bettering knowledge about small groups. Groups should not be conceived, as they sometimes have been in the experimental small-groups literature, as content-free collections of individuals. A content-oriented approach to small groups allows for a systematic analysis of group differences.

In this article, I have been concerned with exemplifying five perceived features of culture content which affect the content of group cultures. It is important to emphasize that these five components produce effects through the interactional negotiation of members, and this negotiation is based upon the shared meanings that these topics of communication have for members. Indeed, each of these five components is itself grounded in situational meanings. Culture is a construction based upon the consensual meaning system of members; it comprises the interactional products that result from a verbal and behavioral representation of that meaning system.

All groups, as they share experience, will develop a particularistic culture. Each of these cultures provides a task for the humanist as well as the social scientist. While we have emphasized the value of

understanding these systems for the comprehension of the dynamics of groups and cultural usage, we have deliberately overlooked the fact that these are also aesthetic systems, and are a product of "artful" communication. At this point we must share our goal of understanding human behavior with the folklorist, the critic, and the poet.

VERTICAL DIFFERENTIATION AMONG OCCUPATIONS*

JOE L. SPAETH

University of Illinois, Urbana-Champaign

American Sociological Review 1979, Vol. 44 (October):746-762

Research on the socioeconomic achievement process has begun to generate anomalous findings, many of which involve occupational status as conventionally measured. Such anomalies include findings on the validity of conventional measures of occupational status, on the sex composition of occupations, and on the effects of occupation on earnings. This paper proposes a theory of vertical occupational differentiation based on the role activities of occupational incumbents. Two dimensions of vertical differentiation, authority and complexity, are derived from the division of labor. These concepts are shown to differ from occupational prestige by estimating confirmatory factor models that contain indicators of authority, complexity, and prestige. Results of the analysis are used to suggest resolutions for the anomalies cited.

Research on the socioeconomic achievement process has begun to generate anomalous findings, many of which involve problems with occupational status as it is conventionally measured. Such anomalies include findings on the validity of conventional measures of occupational status, on the sex composition of occupations, and on the effects of occupation on earnings.

Analyses of the validity of conventional measures of occupational status or prestige show that a regression-based estimate of prestige such as the Duncan (1961) SEI is more valid than direct popular ratings of prestige; that is, the SEI corresponds more closely to an unmeasured occupational socioeconomic status variable than do direct ratings of prestige

(Featherman and Hauser, 1976a; Featherman et al., 1975; Spaeth, 1978). These findings support the "curious implication" that "empirical results . . . are easier to rationalize on the assumption that occupational socioeconomic status is the 'true' measure of occupational status and prestige is a fallible indicator thereof" (Duncan et al., 1972:48-9). The implication is curious because the SEI is constructed by regressing prestige on occupation-specific levels of income and education. In that equation, the predictors are more valid than the criterion.¹

In analyses of earnings, the SEI has been interpreted as an indicator of role performances (Sewell and Hauser, 1975). Moreover,

people perceive . . . accurately that professional and administrative occupations, by their very definition or organization, call for the exercise of greater authority and control and apparently require for their exercise, native and trained capacities and personality traits which craft or operative occupations,

This article is a revision of a paper presented at the annual meeting of the American Sociological Association, San Francisco, 1978. This work was supported in part by a grant from the Research Board of the University of Illinois at Urbana-Champaign and by Grant NIE-G-76-0077 from the National Institute of Education, Department of Health, Education, and Welfare. The opinions expressed herein do not necessarily reflect the position or policy of the National Institute of Education, and no official endorsement by the National Institute of Education should be inferred.

I thank William H. Form, Joan Huber, Kenneth C. Land, and an anonymous referee for criticisms of earlier drafts.

¹ Although Duncan (1961) notes several ad hoc attempts to use prestige ratings as criteria for stratifying occupations, he is quite clear in treating the SEI as a measure of occupational SES and in relating his construction of the SEI to other combinations of occupational levels of education and income and to Edwards's (1938; 1943) construction of a set of occupational categories that could be applied to all censuses starting with that of 1870. In order to validate his social-economic grouping of occupations, Edwards (1943) analyzed the relation of those groupings to education and income.

by their organization, do not. (Featherman et al., 1975:333)

The suggestion that measures of occupational status tap such dimensions of role performance as authority offers a cogent interpretation of their effects, but it does not demonstrate that authority or "other capacities" are measured adequately by conventional measures of status. This suggestion, however, does raise the following questions: Of what dimensions are occupational levels of education and income indicators? What is the relationship of these dimensions to prestige? Can occupations usefully be differentiated according to dimensions other than prestige?

Some evidence for the potential utility of other dimensions of occupational differentiation comes from research on the relationship of sex to occupation. The substantial sex segregation among occupations is well-known (Oppenheimer, 1975; Treiman and Terrell, 1975b), as is the large difference in earnings between men and women (Suter and Miller, 1973; Treiman and Terrell, 1975a). Yet, males and females differ only slightly in levels of occupational status as measured by prestige ratings or by the SEI (Featherman and Hauser, 1976b; Suter and Miller, 1973; Treiman and Terrell, 1975a). On the other hand, Wolf and Fligstein (1979) have shown that men have greater occupational authority than women.

Although monetary returns to occupational prestige are greater for men than for women (Suter and Miller, 1973; Treiman and Terrell, 1975a), occupational prestige accounts for only a small part of the wage gap between men and women—\$124 according to Suter and Miller (1973). A separate measure of occupational authority, on the other hand, helps to account for a substantial part of the sex gap in earnings (Roos, 1978), thereby implying that authority and status are sufficiently distinct dimensions that a serious effort should be made to measure the former independently of the latter.

Other research on the determination of earnings also demonstrates the inadequacy of conventional measures of occupational status. A crude measure of "class" that distinguishes between owners, managers, and workers explains vari-

ance in earnings not explained by occupational status (Wright and Perrone, 1977). The conception of class used in the research cited rests on a highly artificial distinction between the "technical" and the "social" division of labor. The first refers to control over the operation of machines and is held to be occupational. The second refers to control over other workers and is held to be "class." A more parsimonious view holds simply that occupations are the clusters of activities that persons carry out to earn their livelihoods. Supervision of others is just as much an occupational activity as the design, construction, or maintenance of machinery.

The concept of authority underlies this more parsimonious view of class. By controlling the work of others and at the same time not being subject to supervision, owners have great authority. Managers have less authority because they are supervised, and workers have none (Robinson and Kelley, 1979). Reconceptualizing class as authority also establishes linkages between the research just cited and investigations of sex differences between occupations.

These results indicate that conventional measures of occupational status are inadequate and must be reconceptualized. Dimensions of occupation other than status or prestige should be measured in order to capture more fully the effects of occupation on such variables as earnings and to establish the relationship of prestige to other dimensions of occupational differentiation.

This paper proposes a theory of vertical occupational differentiation based on the role activities of occupational incumbents. Two dimensions of vertical differentiation, authority and complexity, are derived from the division of labor, and these are shown to differ from occupational prestige by the estimation of models containing indicators of each dimension.

THE DIVISION OF LABOR AND OCCUPATIONAL DIFFERENTIATION

Dimensions of Occupational Differentiation

The social process that creates differences among occupations according to

role performances is the division of labor. By proliferating tasks, the division of labor creates occupations that vary in their complexity. Task proliferation also creates differences in occupational authority because diverse performances must be coordinated, and coordination implies authority.

As the division of labor becomes more elaborate, occupations become increasingly specialized. On the one hand, the range of tasks allocated to certain occupations becomes narrower until workers spend their time repetitively carrying out simple operations that are small components of larger processes. Cases in point are the manufacture of pins and a modern assembly line (Smith, 1789; Stinchcombe, 1974). On the other hand, other occupations develop through the narrowing of areas of expertise rather than through the narrowing of tasks. Incumbents of these occupations are specialists who do a variety of tasks, all of which are directed to a narrow substantive area, such as a technical or professional specialty. Such "specialists can perform tasks that would not be possible without the expertise available in a narrower field" (Blau, 1977:189). Specialization therefore increases the variation in occupational complexity, from routine jobs consisting of a few simple, repetitive motions to professional and scientific occupations characterized by highly complex work applied to a narrowly defined field.

Occupational authority is created in part by the existence of specialization. The smaller the segments of a process done by individual workers, the greater the need for coordinating them. In modern industrial societies, such coordination is carried out in large-scale formal organizations. These organizations are, of course, hierarchical authority structures, in which positions range from those at the bottom with no authority to those at the top with great authority.

Administrative authority, i.e., authority based on organizational position, is one form of power. Since administrative authority takes place in formal organizations, which are systems of hierarchical offices, it is clearly a specifically occupational form of authority and therefore of

power. To what extent are other forms of power tied to occupations in modern societies?

Blau's (1977) analysis of the distribution of power in modern societies argues that two particularly important forms of power are administrative authority and economic control. The argument rests on Weber's (1968:943) distinction between two forms of domination: "domination by virtue of a constellation of interests" and "domination by virtue of authority" (cited in Blau, 1977:221).

In modern societies, authority is located in bureaucratic positions. Dominance by controlling others through their interests stems from control over economic resources and therefore corresponds to economic control. "Positions of authority over employees are the source of most authority in contemporary societies," and "top positions in organizations with large financial resources are the basis of much control over economic resources in contemporary societies" (Blau, 1977:230, italics omitted). Since positions in bureaucratic organizations are occupations, both administrative authority and economic control are carried out through occupational role performances.

Administrative authority may be operationalized as the number of employees "under the jurisdiction of a given position in a work organization" (Blau, 1977:225). This criterion is a function of the number of organizational levels below a specific position and is therefore a measure of control over the work of others. Another important aspect of organizational authority is the extent to which incumbents of positions may act independently. Thus, the existence of levels above a position implies that the incumbent's discretion is limited.

Economic control may be operationalized as the amount of money or other resources controlled by a person or position—a person's liquid assets or the amount of organizational resources controlled by a position (Blau, 1977:226). Since such control tends to be located in the upper levels of organizations, the absence of levels of authority above a position also may be an indicator of economic control.

Thus, two dimensions of occupational role differentiation—authority and complexity—can be derived from the division of labor. Both dimensions are based on occupational role performances, and both tap vertical aspects of occupational differentiation. If authority, complexity, and, of course, prestige are all vertical dimensions of differentiation, they must be highly related because if correlations between two of them approached zero, it would indicate that these dimensions were orthogonal.² In that case, one of the two would not be vertical.

Relationships between Dimensions

Reasons for expecting authority and complexity to be related pertain to role performances. The relationships of prestige to the other dimensions follow from the nature of popular ratings of prestige and the qualifications of the general public as raters of occupational characteristics.

Occupations with a great deal of authority tend to involve complex tasks. Consider Blau's operational definition of administrative authority as number of employees controlled. The higher the organizational level of a position, the greater the number of persons who will be affected by the decisions taken by its incumbent. Decisions involving large numbers of people tend to be more complex than those involving small numbers because their ramifications are greater. Decisions taken at high levels in organizations such as corporations or government agencies will affect not only many people in the organization but also many outside the organization. Even at lower organizational levels, management involves control over and decision making about highly complex processes. Stinchcombe (1974) shows that keeping a steel-producing plant in operation is a highly complex task. The classic view of

organizations as decision-making structures (March and Simon, 1958; Simon, 1957) implies that positions of authority in organizations entail considerable complexity.

Complex occupations also tend to have relatively great authority. Many complex occupations involve the possession of skills and knowledge not available to persons outside the occupation. This monopoly of skills and knowledge receives legal sanction in the case of the licensing of certain professions. Other occupations restrict access by controlling recruitment. Control of information confers power, and to the extent that this control is legitimated, such power is a form of authority. In addition, certain organizational positions entail control over the knowledge that others need to carry out their work; control over such a resource is a form of power.

Thus, administrative authority and economic control have cognitive components that tend to make such occupations complex; and complex occupations, such as professions, tend to carry considerable authority. Nevertheless, one would expect the relationship between authority and complexity to be imperfect because administrative occupations should rank higher on authority than the professions, and many professions should rank higher on complexity than administration does.

Whereas the relationship between authority and complexity can be derived from role performances, the relationships between authority and prestige and between complexity and prestige cannot. In an attempt to clarify the influence that occupational rewards and perceived value to society have on prestige ratings, Hope (1979) shows that "standard of living" and "value to society" make separate and roughly equal contributions to popular ratings. The same analysis indicates that two dimensions even more central to prestige ratings are "qualifications" and "power and influence" and that prestige lies near the centroid describing this measurement space.

The components of the SEI correspond, at least crudely, to some of these dimensions. Thus, education is a qualification for occupational incumbency, and income

² If the relationship between two variables were curvilinear, their correlation could be zero, but they would not be orthogonal. Monotonic but curvilinear relationships should yield nonzero linear correlations, but other forms of curvilinearity would be evidence that one or both dimensions were not vertical.

is an aspect of standard of living. If the complexity of an occupation is viewed as an indicator of the level of competence needed to perform its duties, complexity can be considered an occupational qualification. Of course, authority is an important aspect of power and influence. Thus, the criteria used by raters of occupational prestige roughly correspond not only to prestige but also to the components of the SEI, as well as to authority and complexity.

Nevertheless, the actual characteristics of occupations should be more accurate indicators of occupational differentiation than popular ratings because they are not filtered through the perceptions of the general public. Although people apparently know enough about occupations to rate various dimensions with a fair degree of consensus (Hodge et al., 1964; Hope, 1979; Treiman, 1977), they do not know enough to rate specific aspects accurately (Evers, 1972; Hodge and Hodge, 1964). Popular ratings of occupational prestige are related to dimensions of role performance, but popular ignorance of specific performances means that the relationships will not be perfect.

The theory proposed here maintains that occupations are differentiated along at least three vertical dimensions that must be highly related if they are truly vertical. Data exist with which to operationalize this theory by estimating models of occupational differentiation.

METHOD

The Data

The data set used here is based on the 323 occupational titles in the 1960 U.S. Census. These data include indicators of complexity and authority from Temme (1975), of authority from four National Opinion Research Center General Social Surveys (GSS), and of prestige based on the NORC studies reported in Siegel (1971).³ The model to be estimated includes indicators of complexity, authority, and prestige.

The source for the indicators of occu-

pational complexity is the *Dictionary of Occupational Titles* (DOT) (U.S. Department of Labor, 1965). From the set of occupational characteristics described in the DOT, three variables have been chosen to reflect occupational complexity: the rated complexity of work with data (DATA), general educational development (GED), and specific vocational preparation (SVP). Rated complexity of work with things (THINGS) is dropped from this analysis for reasons to be discussed later. Rated complexity of work with people (PEOPLE) is treated as an indicator of authority.

DATA varies on an eight-point scale ranging from irrelevant to analyzing ("examining and evaluating data"), coordinating ("determining time, place and sequence of operations or action"), and synthesizing ("integrating analyses of data," USDL, 1965:649).

GED "embraces those aspects of education . . . which contribute to a worker's (a) reasoning development and ability to follow instructions, and (b) acquisition of 'tool' knowledges such as language and mathematical skills" (USDL, 1965:651). This variable has a six-point scale from low ("apply common sense understanding to carry out simple one- or two-step instructions") to high ("apply principles of logical or scientific thinking to a wide range of . . . problems," USDL, 1965:652).

SVP is the amount of time required to learn the "average performance in a job-worker situation." It ranges from one ("a short demonstration only") to nine ("over 10 years," USDL, 1965:652). The intervals of the scale are small at the low end and become greater at the high end. Thus the scale approximates a logarithmic one.

In the DOT, the THINGS scale does not pertain to the full range of occupations. The most complex level of work with things is setting up a machine, which is a highly skilled blue-collar occupation. The three DOT complexity scales have been rescored so that a zero on each indicates that a dimension is irrelevant to performance in a given occupation. If DATA or PEOPLE is irrelevant, the occupation can hardly be very complex, but THINGS is irrelevant to a number of oc-

³ I thank Ross M. Stolzenberg for making these data available.

cupations (Kohn and Schooler, 1978), many of which are white-collar. It would be highly inappropriate to exclude white-collar occupations from an analysis of occupational stratification, so THINGS has been omitted from this analysis.

Although PEOPLE has been treated as an indicator of complexity in other research, it is treated here as an indicator of authority. The scale ranges from a low value for irrelevant to a middle value, supervising, to a high value, mentoring; the last refers to dealing with individuals as whole persons. This corresponds to the kind of authority granted to professionals by their clients.

Two other indicators of authority were computed from the NORC General Social Survey for the years 1972, 1973, 1974, and 1976. In those years, the GSS included questions asking whether the respondent or spouse supervised anyone, and if so, whether their supervisee(s) supervised anyone. These responses were combined into a three-point scale (zero to two) ranging from no supervisory duties to supervision of two or more levels. This variable (MSUP) represents the mean number of supervisory levels below incumbents of each occupation. It is thus an indicator, albeit a crude one, of the organizational location of an occupation.

Respondents also were asked a pair of questions to determine the number of levels above theirs (or their spouse's). Analysis revealed that a simple dichotomy between one or more levels vs. none correlated more highly with other variables than did a three-point scale. This dichotomy is scored one if *no* levels exist above ego's occupation and zero if such levels exist. As a measure of occupational authority, it is therefore the proportion of persons in an occupation who have no one above them. It thus indicates the probability that members of an occupation are independent of a higher authority and is called PIND. If economic control is exercised by top levels in organizations, PIND may be a weak indicator of that concept.

Responses to the four GSS surveys were merged, and scores on MSUP and PIND were calculated for each of the 1960 census three-digit occupational

categories. For comparability with the components of the Duncan SEI, these two variables reflect characteristics of males. They refer to a male's own occupation if he was a respondent or to a husband's occupation if the wife was the respondent and she did not work, so that she reported on her husband's occupation.

Even the merger of four GSSs produced some occupations with very few cases. All categories with five or more cases received the scores computed for that category. All categories with fewer than five cases were combined within major occupation groups according to intermediate classifications (e.g., public administrators were treated as one group by combining local, state, and federal administrators; if necessary, managers, officials, and proprietors were combined across industry). Occupations not falling into intermediate categories were treated as belonging to residual categories with their own scores. The free professions (law, medicine, dentistry, architecture, etc.) were combined into one group on the grounds that persons in these occupations usually supervise at least an office staff.

Indicators of prestige are based on research carried out at NORC. The direct measure of prestige (HSR) is that reported by Siegel (1971) and based on the research of Hodge, Siegel, and Rossi. Siegel also created indicators of the education and income levels of each 1960 census occupation—the proportion of males in each occupation who had 12 or more years of schooling (ED) and the proportion with occupational income of \$5,000 or greater (INC). Thus, these indicators parallel the 1950-based SEI and its components, but they have the advantage of referring to all instead of a subset of the census occupations. In addition, it would have been impossible to use the SEI and its components in this analysis because the multiple correlation between SEI and its components is 1.0 by definition. Means and standard deviations for each indicator are given in the Appendix, along with correlations between the indicators.

The indicators are among the best available, but they are clearly far from ideal. The DOT items are based on the ratings of experts, but no information is available on

the validity or reliability of these ratings. The DOT itself recognizes that the categories of the PEOPLE scale are somewhat indefinite and may not be mutually exclusive (USDL, 1965:649). The authority measures derived from the GSS have several limitations. MSUP encompasses only two levels of subordinates, a degree of differentiation that does little justice to the large formal organizations in which most Americans work. None of the available indicators directly taps economic control, although PIND may tap this concept weakly. HSR, the direct rating of prestige, covers more occupations than any other set of prestige ratings, but some of the occupation names rated by respondents do not closely match 1960 census categories. ED and INC are standard estimators of direct ratings, but they clearly do not tap occupational role performances directly. If analysis based on these indicators supports the theory proposed here, it will show that the theory could fruitfully be pursued using better indicators.

The Models

The main features of an appropriate measurement model already have been mentioned. Three dimensions underlie the nine indicators—complexity: DATA, GED, and SVP; authority: PEOPLE, MSUP, and PIND; and prestige: HSR, ED, and INC. The three dimensions should be highly related; however, each indicator should be directly related only to its specific dimension, although it is, of necessity, indirectly related to the other two dimensions.

The model for the three dimensions is shown in Table 1, in which authority indicators load on authority, complexity indicators on complexity, and prestige indicators on prestige; all other possible loadings are zero. A procedure for estimating this model must allow certain loadings to be constrained to be zero and must allow the covariances between factors (dimensions) to vary freely. The model assumes that the dimensions produce variation in the indicators, so the procedure must provide estimates of the disturbances of the items. Because errors

Table 1. Hypothetical Factor Pattern for Constrained Factor Analysis of Work Characteristics and Prestige Indicators

Indicator	Factor		
	Authority	Complexity	Prestige
MSUP	X	0	0
PEOPLE	X	0	0
PIND	X	0	0
SVP	0	X	0
GED	0	X	0
DATA	0	X	0
HSR	0	0	X
ED	0	0	X
INC	0	0	X

of measurement may be shared by more than one indicator, the disturbances must be allowed to be related to each other. The estimation procedure also should produce standard errors for all coefficients calculated, a test of the overall fit of the model, and diagnostic information for detecting sources of poor fit. Maximum likelihood confirmatory factor analysis, a method of estimation that produces this information, has been developed by Jöreskog (1974) and operationalized in COFAMM, a computer program for confirmatory factor analysis (Sörbom and Jöreskog, 1976).

In order for models of the kind shown in Table 1 to be identified, each factor (dimension) is assigned a reference indicator, which establishes the metric of that factor. The loadings of the reference indicators are constrained to take a value of one. This means that the variance of the reference indicator is one, and all other indicators of a factor are evaluated by comparison with the reference indicator. Even though the loadings of indicators thereby are made comparable, the coefficients are not standardized in the traditional sense—they are rescaled. Other indicators are allowed to vary freely, except that, for each factor, some indicators must be constrained to be zero—a number one less than the number of factors in the model. Coefficients for each factor estimate the extent to which an indicator reflects the factor in comparison with the reference indicator. In Table 1, indicators of other factors are constrained to be zero in order to illustrate the model in its simplest form.

A maximum likelihood χ^2 test compares the variance-covariance matrix estimated from the model with the observed matrix.

The larger the χ^2 , the poorer the fit; a nonsignificant χ^2 shows that a model fits the data well. Two kinds of information are available on sources of poor fit: first-order partial derivatives for each constrained coefficient and a matrix of residuals showing the differences between estimated and observed covariances. The residuals indicate which covariances are estimated badly by the model. If they were to show marked patterning, an additional factor might need to be extracted.

Coefficients are estimated by specifying successively less restrictive models until the variance-covariance matrix estimated by a model does not differ significantly from the observed matrix. First, the "pure" model with hypothesized loadings only (see Table 1) is estimated. Then, some of the coefficients that initially were constrained to be zero are allowed to be free. Which coefficients are freed is determined by the values of the partial derivatives. In general, factor loadings are freed first, followed by the correlations between residuals; but the final stage of model fitting alternates between freeing loadings and residual correlations. When an acceptable fit is obtained, coefficients are compared with their standard errors, and insignificant ones are omitted.

Two models are estimated here. The first pertains to relationships among role performances only and therefore contains indicators of authority and complexity but not prestige. The second contains indicators of all three dimensions.

RESULTS

The first model to be estimated deals with the indicators of role performances. As Table 2 shows, MSUP, PEOPLE, and PIND load strongly on authority; GED, SVP, and DATA load strongly on complexity. These findings are in accord with the authority and complexity parts of the model shown in Table 1. Although DATA and SVP have small but significant loadings on authority (.154 and -.149, respectively), their loadings on complexity are much larger (.780 and 1.0). Similarly, the modest negative loading of MSUP on complexity (-.210) is much smaller than

Table 2. Constrained Factor Analysis of Indicators of Occupational Authority and Complexity

Indicator	Factor	
	Authority	Complexity

PIND	.420	0
SVP	-.149	1.0
GED	0	.971
DATA	.154	.780
$\chi^2 = 4.787$, d.f. = 5, $p = .442$		

its loading on authority, a factor for which it is the reference indicator. Although the factors are basically distinctive in item composition, the correlation between the two is .840 (see Figure 1).

The model that produced the results in Table 2 allows for the presence of correlations between disturbances. Only two of these are statistically significant: PEOPLE-SVP (-.108) and PEOPLE-PIND (.247). The fit of the model is excellent, as shown by a χ^2 of 4.787 with five degrees of freedom.

Adding the indicators of prestige to those of complexity and authority produces estimates that continue to suggest that the dimensions of occupational differentiation are distinctive (see Table 3). The pattern of loadings for authority and complexity is quite similar to that in Table 2. MSUP is the reference indicator for authority, with PEOPLE and PIND having loadings similar to those in the two-factor solution (.609 and .413, respectively). SVP has a small negative (-.135) and DATA a small positive (.160) loading on authority. The pattern of loadings for complexity is also quite similar to

$\chi^2 = 4.787, d.f. = 5, p = .442$

Figure 1. Model of Vertical Role Differentiation among Occupations

that in Table 2. SVP is the reference indicator, with GED having a loading nearly as large (.993) and DATA a substantial loading (.786). As with the two-factor solution, MSUP has a modest negative loading on authority (-.177).

The third factor clearly measures prestige. HSR is the reference indicator, with ED having a substantial loading (.747) and INC a slightly smaller one (.691). In addition, ED has a modest loading on complexity (.201) and INC a small (and not significant) loading on authority (.125). The loading of INC on authority was allowed to remain in the model because, together with the loading of ED on complexity, it tends to explain why the Duncan SEI seems consistently more valid than ratings of prestige. The components of the SEI apparently tap dimensions of occupational differentiation other than prestige. The fit of the model is very good, with a χ^2 of 18.088 and 15 degrees of freedom.

The three factors are highly but not perfectly correlated: authority-complexity = .813, authority-prestige = .779, complexity-prestige = .739. With standard errors of .032, .032, and .028, respectively, the difference between each of these correlations and 1.0 is highly significant statistically. The three factors are not "congeneric"; that is, they are not equivalent measurements of the same thing (Jöreskog, 1974:5).

Of the seven significant correlations between residuals, only one is sizable, that between PEOPLE and PIND (.263). Since the two items are indicators of the same dimension, authority, there is no evidence of the need for another factor in these data. All other significant correlations among residuals approximate .1.

The size of the residuals themselves casts some light on the unreliability of MSUP and PIND, the two items constructed from the GSS for this analysis. The reliability of these indicators is at issue because the minimum number of cases required for an occupation to form a separate category of its own was five. Because of their aggregation, these data on occupations should be more reliable than the same data on individuals (Robinson and Kelley, 1979; Roos, 1979), but five

cases is not a large number. The residuals themselves (Figure 2) have two components, unreliability and specificity, which are not separable in this analysis. Considered as estimates of unreliability, therefore, the residuals are maxima. The maximum unreliability for MSUP is therefore .249, which compares favorably with the .236 for SVP, the .228 for ED, and the .399 for INC. Given that ED and INC are census-based estimates, the reliability of MSUP seems to be reasonably high.

Taken as an indicator of unreliability, the .832 for PIND is quite high. However, the actual survey questions on which MSUP and PIND are based imply that the reliability of the two indicators should be approximately the same. For MSUP, respondents reported on the existence of at least one subordinate and whether that person had at least one subordinate of his or her own. For PIND, respondents simply reported on the existence of a supervisor. There seem to be no grounds for assuming that respondents' accuracy would be drastically less for reporting supervisors than subordinates. It seems more reasonable to assign the differences between these coefficients to specificity. Given the size of the residuals for PEOPLE (.646) and INC (.399), other indicators also may have large specific components.

The results reported so far yield little information on why certain indicators have substantial specificities. An analysis that included the percentage of males in each occupation provides several useful clues to specificity. Most of the results of this analysis will not be reported in detail because they confirm those already presented. Salient differences in loadings between the three-factor model already presented and one in which the percentage male initially is allowed to load on all three factors are limited to the following: the percentage male has a small (.113) and marginally significant (standard error = .052) loading on complexity; it has no significant loadings on the other two factors. ED does not have a significant loading on complexity, nor does INC have a significant loading on authority. Otherwise, the pattern of loadings in the model with per-

$\chi^2 = 18.088$, d.f. = 15, $p = .258$

Figure 2. Model of Vertical Differentiation among Occupations Incorporating Prestige

centage male is closely similar to those in the model without this variable. Furthermore, the correlations between factors are virtually the same. The fit of the model is given by a χ^2 of 23.536 with 19 degrees of freedom; $p = .215$.

Correlations between the residuals of percentage male and the other variables provide information on the specificity of some of these variables. Table 4 shows zero-order correlations and correlations of residuals with percentage male. The zero-order correlations show rather clearly why percentage male loads only on complexity. Of the three sets of three indicators, those for complexity are the only ones to have consistently positive correlations with percentage male. Among indicators of authority, PEOPLE is negatively correlated with percentage male, as is ED among the indicators of prestige. For the most part, correlations of the residuals reflect the zero-order correlations, but the significant correlations are particularly instructive. There are four such correlations—percentage male with PEOPLE, SVP, ED, and INC. The last three of these clearly indicate that the specificity of a variable resides at least partly in its manifest content, as opposed to the dimension of which it is an indicator. Thus, SVP is the amount of time required to learn a job; it is positively related to percentage male. Because women's labor force participation is more sporadic than men's, the latter are exposed to a greater "risk" of being in the labor force long enough to accrue the experience necessary to qualify for occupations that re-

quire long periods of special vocational preparation. ED, on the other hand, reflects the higher levels of education attained by women, at least through 1960. Recall that ED is the percentage of persons in an occupation who had completed 12 years of schooling. Women's greater average levels of education were manifested by their greater probability of graduating from high school (Folger and Nam, 1967). The sizable coefficient for INC (.288) reflects one of the problems on which this analysis attempts to throw some light. Men are concentrated in occupations that pay better than the ones in which women are concentrated.⁴

The negative correlation between the residuals of percentage male and PEOPLE presumably stems from a confounding in the DOT between two aspects of occupations dealing with people. In the first place, of course, a crucial aspect of on-the-job social interaction is the giving and taking of orders. In the second place, women are concentrated in occupations that involve interacting with others as part of the duties. Part of the PEOPLE scale taps the first aspect and brings about its substantial loading on authority. Another part taps the second aspect and is reflected in the negative correlation with percentage male. In both the analysis that includes percentage male and that in which this variable is absent, the correlations of the residuals of PEOPLE with PIND is .26. Apparently the variables tap an authority-related concept other than the general level of authority characteristic of occupations.

In general, the intercorrelations of the residuals of percentage male with those of the other variables highlight the weakness of some indicators. This weakness probably results in part from the fact that the indicators are used here in ways quite

Table 4. Zero-Order Correlations and Correlations of Residuals of Indicators of Authority, Complexity, and Prestige with Percentage Male

HSR	.126	ns
ED	-.056	-.151
INC	.388	.288

⁴ Whatever the virtues and drawbacks of using aggregate levels of education and income to estimate prestige, as in the SEI, and then using prestige in individual-level models as an effect of education and a cause of earnings, the "finding" that men tend to be concentrated in high-paying occupations raises the following problem: What are the characteristics of men's occupations that make them pay well? Using the income composition of these occupations as an explanation would clearly be tautological.

different from the purposes for which they were created. An additional source of weakness is the crudity of the indicators themselves. In particular, the indicators of authority clearly fail to do justice to that concept.

DISCUSSION

This paper shows that there are at least three dimensions of the vertical differentiation of occupations: authority, complexity, and prestige. These dimensions are highly related (interfactor correlations are about .8) but compositionally quite distinct. Although these results must be treated as provisional because of the crudity of the indicators and specific components of some of them, the results point to the advantages of a disaggregated approach to occupational SES.⁵ Among the issues raised by this perspective are the interpretation of prestige, the analytical utility of authority and complexity, and further development of measures of these dimensions.

Prestige is not the same thing as authority or complexity; it is a distinct dimension of occupational differentiation. Furthermore, the components of the SEI are direct indicators of prestige but not, for the most part, of the other two dimensions. Given the results of this analysis, occupational prestige should be treated as an indicator of the perceptions of the general public, and the SEI should be treated as an indicator of prestige. If such characteristics of occupations as authority and complexity are important variables in an analysis, these characteristics should be measured directly.

Some ways in which direct measures of job characteristics may be preferable to prestige ratings already have been mentioned. Measures of authority reflect the sex segregation of occupations far more closely than does prestige. Thus, in the Wisconsin data on high school graduates, 28% of the men and 9% of the women have the authority to hire and fire; 37% of the men influence the pay of others, compared with 14% of the women; and 61% of

the men supervise others, compared with 38% of the women (Wolf and Fligstein, 1979).

With a typology based on the two GSS indicators of authority used here, Roos (1979) has accounted for 58% of the sex gap in earnings, with most of the difference due to authority and other occupational characteristics and none due to prestige.⁶ Even these results may underestimate the effects of authority. An analysis of the earnings gap in a single firm found that discrimination in earnings between the sexes was completely explained by level of job responsibility (Malkiel and Malkiel, 1973).⁷

In addition to confirming the importance of authority as a determinant of earnings, Roos's (1979) results also support the interpretation of the SEI as a measure of prestige. In separate sets of equations, the effects of the SEI and HSR on earnings were undistinguishable and became nonsignificant when other occupational characteristics entered the analysis.

Complexity is important for other reasons. It is a dimension of the intergenerational transmission of status characteristics (Spencer, 1977) that explains the effects of parental SES on intelligence and part of the effects of parental SES on education (Spaeth, 1976b). Moreover, the complexity of one's work at one period increases one's intellectual flexibility as well as the complexity of one's work at a later period (Kohn and Schooler, 1978). Thus, an important intrinsic aspect of work is self-reinforcing.

Another way in which the effects of authority and complexity may be self-reinforcing lends itself to a human capital

⁵ Compare the arguments for treating the traditional components of SES in a disaggregated manner (Duncan et al., 1972; Hauser, 1972).

⁶ Unfortunately, the median earnings of males was one of the occupational characteristics added. This variable had a substantial impact on the earnings of both men and women, whether the SEI or HSR was controlled. It is possible that this independent variable is confounded with the dependent variable but also that the effects of authority on earnings and on the earnings gap are underestimated. On the other hand, the decomposition of the earnings gap attributable to occupational characteristics other than prestige is not necessarily attributable to authority.

⁷ The measure of responsibility was a firm-specific one that was highly correlated with pay. Part of this correlation could easily have been an artifact of company policy.

interpretation. The importance of occupational experience in the determination of earnings is a fundamental tenet of human capital theory (Becker, 1975; Mincer, 1974), and occupationally relevant experience has been shown to be more important than total experience as a determinant of earnings (Griffin, 1978; Spaeth, 1976a). Experience is important because it is an indicator of on-the-job training, which is an investment that produces earnings returns.

One may hypothesize that the "quality" of work experience should be an especially important determinant of earnings and that experience perceived to be relevant should be particularly important if it is in occupations with high earnings potentials. Such occupations should be high on authority, complexity, or both. Experience with authority and complexity produces increments in the ability to handle authority and complexity. From the worker's point of view, demonstrated competence on either dimension is evidence that he or she should be promoted to a higher level. From the employer's point of view, demonstrated competence on either dimension is evidence that the worker is ready for promotion. This hypothesis could be tested by constructing a measure of quality of experience using a career history to ascertain the amount of time spent on each job, by weighting time spent on the job according to the complexity of the work and the amount of authority entailed in each job, and by summing the weighted scores over the career. This variable should explain earnings better than a combination of temporal experience and the perception of relevance. Interpreting authority and complexity as indicators of quality of experience suggests a reasonably straightforward human capital interpretation of the importance of these dimensions. Unless prestige is considered a surrogate for one of these dimensions, it is difficult to formulate a similar explanation for its effects.⁸

Although currently available indicators of authority have greatly enhanced our

understanding of the effects of occupations, these indicators are extremely crude. The growing literature on the effects of authority and the present results on the importance of authority as a dimension of occupational differentiation make the development of better indicators of authority a logical next step.⁹ The following brief discussion proposes an approach to the development of such measures. For these purposes, authority is viewed as legitimate control over work situations, including control over the work of others, control over one's own work, and control over occupation-linked resources.¹⁰ The first form of control corresponds to administrative authority and the second to autonomy. The third corresponds to Weber's (1968) economic control.

A starting point for the measurement of administrative authority is Blau's (1977) operationalization of this concept. Needed here would be information on the total number of levels below an occupational incumbent and the number of employees whom he or she controls. Such control would have to be defined in broader terms than supervision because greatest power is exercised indirectly through intermediaries (Blau, 1977:218). Also included in this concept would be designing work procedures plus promulgating and enforcing work rules. Further indicators of administrative authority could be participation in decisions about hiring and firing and about pay (Wolf and Fligstein, 1979), as well as other aspects of the design and application of systems of evaluation (Dornbusch and Scott, 1975).

⁹ This discussion is not intended to denigrate the importance of complexity. Available indicators of complexity are based on expert observations. Measures of authority (except for PEOPLE) are based on survey respondents' reports on their own work. Although persons can presumably report such factual matters as the presence or absence of supervisors with some accuracy, their perceptions of the difficulty of their work might be highly subjective. Since complexity is essentially the cognitive difficulty of the work, one would expect ratings of such work aspects to be inaccurate. This discussion therefore concentrates on the derivation of indicators of authority.

¹⁰ Wolf and Fligstein (1979) propose a similar scheme that distinguishes between control over the work of others and oneself plus capital. Since organizational resources are not limited to the monetary and since some monetary resources are not capital, the distinction proposed here is somewhat broader.

⁸ See Sawyer (1978) for an attempt to provide a human capital interpretation of prestige that treats prestige as a surrogate for complexity and autonomy.

Indicators of autonomy could include the presence or absence of supervisors as well as the closeness of supervision for persons with supervisors. The application of evaluation procedures also could be important. Occupational incumbents evaluated on the results of their work should have more autonomy than those evaluated according to conformity to established procedures (Dornbusch and Scott, 1975).

Control over resources would include control over capital, such as making investment decisions for a firm. Other indicators could be the size of a department's budget (as a characteristic of heads of departments) and the amount of money that an occupational incumbent could disburse without the approval of higher authority.

Another particularly important resource is information. Persons at communications "nodes" in organizations can have considerable power, and if the transmission of information is one of the duties of a job, the power is legitimate. Occupying a "boundary spanning" role (Thompson, 1961) may be a particularly important instance of the control of information. Such roles, which involve negotiating with other organizations and keeping members of one's own organization informed of the results, may have considerable authority (Aiken and Hage, 1968; Goldner, 1970). It also should be noted that the boundaries between departments may be spanned within an organization. Incumbents of occupations whose duties include such activities also should have considerable authority.

This preliminary attempt to derive indicators of authority is analogous to that adopted elsewhere in this paper. In order to understand the vertical differentiation of occupations, and therefore the nature and effects of occupations, one must postulate a set of dimensions and attempt to operationalize them. This approach can also be applied to the derivation of sub-dimensions, such as those proposed for authority.

Methodologically, the proposed procedures correspond to hierarchical factor analysis,¹¹ an approach that also applies to the relationships between authority, complexity, and prestige. The high correlations among these variables argue that they may be considered as dimensions reflecting a single grand factor—occupational SES. In suggesting this perspective, an anonymous referee has aptly described such a concept as a "black box" that accounts for the three dimensions. This critic also suggests that, given the general concept, the dimensions themselves are no longer necessary. The reverse is probably closer to the truth. Without conceptions of distinct dimensions, the black box will remain opaque and its contents unknown. It is through attempts to operationalize dimensions of vertical occupational differentiation—occupational SES—that the meaning of this concept can be empirically explicated. This paper has made a start in this direction, but much remains to be done.

¹¹ For a general discussion of hierarchical factor analysis, see Nunnally (1978). For an application to measured intelligence, see Cattell (1971).

PRIEST RESIGNATIONS IN A LAZY MONOPOLY*

JOHN SEIDLER
Ohio State University

American Sociological Review 1979, Vol. 44 (October):763-783

This paper examines the structural antecedents and consequences of diocesan resignation rates among American Catholic priests during the period 1966-1970. A national survey with a 74% return rate (941 priest-informants) yielded usable data on 131 American Catholic dioceses—i.e., 96% of the population as defined. Resignations appeared to derive directly from the following diocesan conditions: percentage of parishes run by religious clergy, regional dominance (i.e., status of dioceses as "province"), percentage Catholic in area population, percentage of diocesan priests engaged full-time in nonparish work, and estimated degree of priest passivity and disillusionment. Indirectly, traditional authority structures, ideological divisions, and the absence of social solidarity also increased the probability of resignations. Resignations appeared to have no immediate feedback effect on episcopal policies. Such findings are in partial accord with other research indicating a deprivation syndrome leading to resignations. But the special salience of facilitating, rather than causative, factors, along with the absence of feedback, strongly suggests that the Catholic church of that era was a lazy monopoly. Such organizations are slow to make essential changes; they allow radical personnel to depart rather than deal with their criticisms.

Priest resignations have been a recent object of scrutiny by sociologists. Several authors, studying resignations in a social psychological framework, have analyzed attitudes preceding resignation (e.g., Schallert and Kelley, 1970; Schoenherr and Greeley, 1974). Such investigations also have had organizational implications. For example, Cyrns (1970) implied that the clergy climate was overly dogmatic. Schallert and Kelley (1970) suggested that the institutional rate of change was too slow for progressive clergy. Schoenherr and Greeley (1974) implied that Vatican absolutism on priestly celibacy resulted in a burdensome structure of clergy life. All of these studies suggest that the structure of ecclesiastical Catholicism constituted a stumbling block to continued commitment of many American clergy, at least for the period of the late 1960s and early 1970s.

Other authors more directly investigated the organizational environment of priestly life and commitment. Hall and Schneider (1973) portrayed a dismal work structure for assistant pastors in one diocese during the same period.¹ Goldner et al. (1977) suggested that the Catholic church's recent open communication system, while aligning Catholicism with contemporary democracy, has had indirect negative consequences. Negatively for the organization, open communications have produced cynical knowledge and lessened commitment among lower clergy and other constituents. According to Goldner et al. (1977:540), cynical knowledge is the understanding that presumably altruistic organizational activity actually serves the maintenance of the institution.

These studies suggest a triple possibility for the influence of ecclesiastical structures on priest resignations. These structures may (1) directly cause resignations, because they are organized contrary to professional norms; (2) indirectly facilitate resignations, though organized in accordance with professional norms; or (3) be irrelevant to resignations. There are

This research was supported in part by funds made available through a National Science Foundation Science Development grant to the University of North Carolina at Chapel Hill. I wish to thank the following people for their helpful comments on earlier drafts: Hubert M. Blalock, Russell R. Dynes, Gerhard E. Lenski, Katherine Meyer, Richard L. Simpson, and anonymous reviewers. I also wish to thank Robert Szafran for comparing my data with the Schoenherr-Greeley data.

¹ It should be noted that that diocese has made major modifications in the work structure of priests since that study, and in answer to the problems pointed out in the study.

surely other possible relationships, but these three will give focus to the current investigation.

Other authors have considered the consequences of priest resignations. Fichter (1974), NORC (1972) and McClory (1978) all pointed to the institutional crisis induced by recent resignations combined with seminary losses. Fichter, however, conveyed a tone of optimism about future church structures, partly because he noted and promoted the direction of renewal—toward increased clergy professionalism and greater democracy. At the same time, many of these writers (e.g., Greeley, 1977; chap. 8) depicted a rather conservative set of American bishops who have overlooked the institutional crisis and continued to act in a traditional manner.

These and similar studies suggest three possible consequences of priest resignations: (1) they may create a conservative backlash by bishops; (2) they may promote modernization; or (3) they may be irrelevant to diocesan structures.

The study presented here (concentrating on diocesan priests and the diocesan structure in the United States) will investigate the six possible relationships mentioned above between church structure and priest resignations. The period of analysis is 1966–1970—the same period of time studied by the authors treated above. This study will consider also various models of organization to which the diocesan (and other) church structures may have conformed during that era, as implied by the findings.

This paper argues that the findings, in many ways surprising, can best be interpreted by applying the concept *lazy monopoly* to the Catholic diocese, and even to international Catholicism. The lazy monopoly thus is used as a model to summarize a good deal of the findings, and will be discussed later in the paper.

EXTENT OF RESIGNATIONS

Resignations of clergy became a new problem for the Catholic church in the late 1960s. Resignation rates rose gradually among diocesan priests in the United States from about .1% annually in the

1940s and 1950s to about .5% in 1965 and 2% in 1969 (NORC, 1972:277; Schoenherr and Greeley, 1974:408).

Net losses to the active clergy only very recently have become apparent. Though an estimated 10% of clergy resigned the active ministry between 1966 and 1972 (Schoenherr and Sørensen, 1975), *net* losses appeared to be smaller, probably due to replacement by new ordinands, postponed retirements, and other factors. Fichter (1974:22), for example, notes a net loss of only 2.5%, from 59,892 American Catholic priests in 1967 (the peak year) to 57,421 in 1972. But, with numbers of diocesan seminary students drastically down, from 26,200 in 1966 to 13,600 in 1972 (Schoenherr and Sørensen, 1975), the problem of priest replacement has become increasingly acute. Thus, the most recent estimate of net losses among active American clergy (McClory, 1978) is 14%, from about 59,000 in 1966 to about 51,000 in 1978; these figures obviously reflect the combination of high resignation rates and low replacement rates.

But even in the early 1970s the problem was noticeable to many. According to my own data, 24 dioceses lost 10% or more of their priests to resignations during the period 1966–1970, and one diocese lost almost 19% in this way. In the larger context, too, the problem was there; religious professionals, including nuns, were not so abundant as before. Resignation rates for priests belonging to religious orders (those not directly subject to a bishop) were even higher (Fichter, 1974:22; NORC, 1972:277), and the decrease in total church professionals from 1966 to 1972 was 15.3%, according to official church statistics (Fichter, 1974:21).

ANTECEDENTS OF RESIGNATIONS

In keeping with the distinction, made above, between directly causing resignations and indirectly facilitating resignations, antecedents were labelled as either *causes* or *facilitators* of exiting. Of course, the causal nature of an antecedent cannot be established with certainty, and the dividing line between cause and facilitator is somewhat arbitrary. Nevertheless, the distinction seemed useful.

Causes were those antecedents deriving from a constitutive theory of commitment: that is, they reflected social conditions thought necessary to maintain morale or a viable network of professionals. As suggested earlier, causes of resignations might consist of a structure organized contrary to current professional norms.

Facilitators, on the other hand, were antecedents deriving from nonconstitutive theories about commitment; that is, they reflected social conditions which might influence commitment but which were not ordinarily considered an integral part of commitment. In addition, they might even consist of a structure organized in accord with professional norms, as mentioned above.

The present investigation took Schallert and Kelley's study as the starting point for developing antecedent structural variables. According to Schallert and Kelley (1970), the decision to resign the ministry arose from an atmosphere in which change-oriented priests were frustrated with ecclesiastical structures. Resignees, over 300 of whom were interviewed in depth, embraced the values of individual freedom, less rigid authority, personalism, evolution of dogma, a pastoral orientation, and a dynamic view of structures. Frustrated in attempting to live by these values, and alienated, they decided to resign when a crucial other, symbolizing the ministry, let them down.

Most of these conditions—authority patterns, freedom, pastoral and change orientations—were largely determined by the Ordinary (chief bishop) of a diocese. These and other bishop-related conditions of the clergy climate were included in the present study. In fact, four categories of structural conditions were included, in an effort to investigate causes and facilitators of resignations.

First were three conditions indicating episcopal policies. They were democratic leadership by the Ordinary, clergy autonomy, and negative sanctions. These (or their opposites) would be considered causes of priest resignations under two constitutive theories: (1) an increasing norm of church democratization and clergy professionalism, requiring an appropriate climate for priest commitment

(Schallert and Kelley, 1970; Fichter, 1974); and (2) the inappropriateness of negative sanctions in a normative organization (Etzioni, 1961).

Second were five conditions indicating the informal climate among clergy, but still reflecting the bishop's style. They were ideological polarization between bishop and lower-level clergy, cross-status friendships among clergy, friction initiated by lower-level clergy and aimed at the bishop, solidarity among dissident priests, and priest passivity and disillusionment. These, too (or their opposites), could be considered causes of priest resignations under various explanations requiring consensus or social solidarity for continued commitment (Fichter, 1974).

Third was a set of mostly stable, nonbishop-related conditions reflecting the environment or general diocesan salience. They included the urban concentration of a diocese, relative size of the Catholic population of the area, diocesan size, and regional dominance (i.e., whether the diocese was a regional bureaucratic center for ecclesiastical matters). None of these conditions (or their opposites) could be considered a cause of priest resignations, since most people do not regard them as absolutely essential for a viable clergy. Yet they could perhaps trigger or facilitate resignations. For example, an urban environment could raise clergy consciousness about other career options.

Finally, there were five characteristics of the formal structure which were at least potentially policy matters of the bishop, but tended to be relatively stable during this period, due to diocesan size, traditional structural arrangements, and long-standing commitments of personnel. They were average number of priests per parish, average length of service before becoming pastor, task specialization (percentage of priests in nonparish work), size of the priest teaching corps, percentage of parishes run by religious clergy (i.e., priests whose main allegiance is to a religious order and not the episcopal structure—e.g., Dominicans, Franciscans, Jesuits). Some of these variables could be considered causes of priest resignations, since they might trigger dis-

satisfaction with career advancement or job satisfaction (Hall and Schneider, 1973); others would probably be facilitating conditions, indirectly leading to dissatisfaction.

Although all of these conditions were possible antecedents of priest resignations, some explanations seemed more likely than others. Episcopal policies and clergy climate were expected to be the major determinants of priest resignations, partly because of Schallert and Kelley's (1970) findings and partly because of a similar pattern found to hold for explaining priest protest aimed at bishops (Seidler, 1972). In addition, the bishop seemed quite salient in those days. In the late 1960s, conditions set rather directly by the Ordinary seemed crucial. Authority problems were paramount. Clergy constantly discussed the way bishops treated their subjects, how frequently sanctions were administered and whether they consisted of nondesirable transfers and other punishments. Priests compared dioceses to discover if the bishop ran each location on fear or whether in other places he aimed at consensus governing. Certainly leadership policies, whether democratic, punitive, or respectful of clergy autonomy, would be crucial in holding clergy to their priestly commitment. Certainly compliance structures that underscored normative consensus and the use of rewards rather than punishments would increase priestly satisfaction with their work. Surely a socially integrated diocese—with lower-level priests sharing friendship with the bishop and his staff—would prevent resignations. Such structural conditions deriving largely from the bishop's leadership policies appeared early as the best explanation of priest resignations.

CONSEQUENCES OF RESIGNATIONS

Using the same sets of variables, and regarding them as a dynamic system of interplaying conditions, I investigated the feedback of resignations upon the features previously considered as antecedents. Thus the same variables came under consideration, with the exception that those

under categories three and four (the more stable characteristics of structure and environment) seemed too stable to be reactive.

Resignations obviously could have a variety of structural consequences. Solidarity might increase with the loss of troublemakers. Or disillusionment might grow with the feeling among those who remained that leaders did not make concessions to justifiable demands of potential resignees. Policies might tighten in the hopes of denying freedom and temptation to other clergy, or policies might relax as a sign of increased trust in the faithful remnant.

One could argue that bishops who suffered the greatest loss of resigned priests would get the message and set up a more democratic, progressive clergy climate. Such is implied by Hirschman (1970), who emphasizes the symbolic nature of exiting (resigning). Managers (here bishops) who experience increased exiting will realize that clients or members are displeased with the product or organization. Efficient and competitive managers will try to cut losses by changing policies in favor of a more desirable product or organization.

In this case, however, I expected differently. Judging by a similar feedback from priest protest, I thought any change triggered by resignations would be towards less democratic leadership, less clergy autonomy, and perhaps increased use of negative sanctions by the bishop, rather than towards a more democratic policy. The bishop would probably assume that too much freedom resulted in the temptation to withdraw commitment. I knew also that bishops were generally rated as strikingly more conservative than lower-level clergy (Seidler, 1972), and so I expected such restrictive policies to reflect the natural tendency of traditionalists trying to curb liberals. In addition, the long run impact of seminary and clergy shortages were not yet apparent.

Secondarily, however, I expected the informal clergy climate to be improved by priest resignations, since presumably the marginal and divisive priests would have resigned and thus allowed for greater overall solidarity among remaining clergy.

MODELS OF THE CHURCH

Models of the church abound in general studies of Catholicism especially regarding the locus of authority. Fichter (1974:61-3) maintains that the church, considered as a worldwide structure, is in transition from a pre-Vatican monophasic system (all power centralized at the Vatican) to a polyphasic one (a decentralized and representative form of organization), in which the basis of organizational solidarity becomes consensus rather than loyalty to the hierarchy (81). Greeley (1977) seems to stress that the church is still formally an international monolith, when he underscores the importance of the pope's birth control decree, and the crucial impact of the pope's American delegate. But at the same time he points to an informal, communal and ethnic structure within the formal structure.

Theologians and pastoral planners, too, suggest a plethora of church models, but they generally describe a tension between hierarchical and more democratic structures which are theologically justified and only slowly gaining ground in practice. Küng, for example, describes certain continuing features as absolutistic or monocratic (Küng, 1976:520-1), while he opts for a pluriform church in the ideal (Küng, 1976:475-509). Dulles (1974), too, scores the monopolistic tendencies of the church which operated largely as a closed society, while he looks for an authority of service, shared responsibility, and subsidiarity, or local variation.

Models of other structural features, such as communication and common clergy understandings, also are discussed. Goldner et al. (1977) suggest a change in the church from monolithic control over explanations of ecclesiastical actions to a more democratic communication system in which official and counterofficial interpretations compete for acceptance by clergy. More and more, hierarchical structures are viewed as engaged in ordinary political activity instead of divinely inspired actions to be revered. Greeley, without using the same label, also has underscored the growth of cynicism, especially in his treatment of the consequences

of the pope's birth control decree (Greeley, 1977: chap. 7; Greeley et al., 1976). A variety of models, then, have been utilized to analyze the changing situation of authority, idea exchange, and common perception among American Catholic priests.

Models of the church also were implied in the expectations discussed above as antecedents or consequences of resignations. First, I have generally assumed the relative autonomy of each diocese, with the Ordinary able to lead in an autocratic or democratic way, as he chooses. In this sense, the international church was not seen as a complete monolith or monophasic system centered in Rome, but as at least partly polyphasic. Subsidiarity or home rule was the assumption, so that clergy commitment and climate were dependent upon what happened in that diocese, which was viewed as a major center of action.

Second, the above expectations also implied a transition from monocratic leadership style to a democratic one at the diocesan level. Since new democratic principles were emphasized at the Vatican Council, priest hopes for changes in that direction were expected to influence the clergy climate. In dioceses where democratic leadership and informal solidarity existed, clergy commitment would be firm; where autocratic authority and hierarchic divisions continued, clergy commitment would slip.

Third, these models also implied a relatively closed social system. Internal influences, such as authority style and informal clergy climate, were thought to exert salient influence, while environment or other relatively stable aspects were seen as contributing minor impact. In addition, critical problems, such as clergy protest or resignations, were expected to be handled functionally by the authority structure.

Fourth, a pluriform church was implied, as local variations in leadership style and interpretations were viewed as substantial. Each diocese seemed to be its own unique mini-church.

Finally, these expectations implied that dioceses in which priests remained strongly committed were headed by ad-

ministrators (bishops) who minimized the production of cynical knowledge. They presumably accomplished this by modernizing local structures and infusing them with the spirit of Vatican II, thereby defusing clergy criticism of ecclesiastical self-interestedness.

HYPOTHESES

Specific predictions are summarized in Table 1, relating structural conditions to resignations in both antecedent and consequent direction. In addition, a more detailed causal model showing predicted direct and indirect relationships was developed. In order to save space, the details of that model are not given here.

METHODS

1. Data Sources

I used two data sources for information on dioceses. The first was my own survey of 1,279 diocesan priests in all 137 Latin-rite dioceses that had ten or more diocesan priests at that time (1966-1970). The

survey mailed in February 1971 yielded a return rate of 74% (941 usable questionnaires). These questionnaires then were combined within each diocese to create diocesan scores.

Questionnaires in this survey were brief and they elicited information mostly about clergy relations and events of the immediately preceding five-year period, which began with the completion of the Second Vatican Council (December 1965). Resultant variables are listed in Appendix 2 as X_1 - X_9 .

The second data source was a directory of basically demographic traits of American clergy (Luzbetak, 1967). Since these data referred to relatively stable structural conditions as they existed in 1966, the first year of the observation period, they were used as antecedent conditions in the analysis. These variables are listed in Appendix 2 as Z_1 - Z_9 .

2. Sample of Priests

In each diocese, my questionnaires were sent to ten priest-informants who were chosen after a detailed preliminary investigation (see Appendix 1). For comparability of judgment, I chose priest occupants of ten different structural positions in each diocese, including one member of the Priests' Senate or Council, a Newman Chaplain, a member of the liturgy Commission, a member of the information staff, and a Dean or Vicar. All informants were priests beneath the rank of bishop and below the position of chancellor. The selection of a range of positions (excluding extremes) was intended to reduce reporting bias (see Appendix 1).

3. Questions

Fixed-answer questions focused on clergy relations, especially the authority climate. For example, informants were asked to rate the religious progressivism of the Ordinary and the degree of camaraderie among various groups of clergy. They also were asked to recall the number of priests who had resigned the priesthood during the previous five years—occurrences which were much discussed in the priestly grapevine during those days.

Table 1. Predicted Impact of Structural Variables on Resignations and Vice Versa

Staffing by		
Religious Clergy	+	
Teaching Corps	+	
Priests in Nonparish Work	+	

4. Reliability

For this kind of data, reliability of information seemed solid. Average internal consistency among informants within each diocese was .8, according to an adaptation of the split-half reliability formula. (For details of this and other aspects of reliability and validity, see Appendix 1.)

5. Assigning Diocesan Scores

For each item diocesan scores were created by averaging responses given to that question by priest-informants of that diocese. Since these responses concerned diocesan conditions and climate, they were considered structural estimates from the beginning, without need of transformation from individual to organizational unit of analysis.

6. Sample of Dioceses

This survey sampled all 137 dioceses as defined. And the definition eliminated only eight dioceses, either because they had fewer than ten diocesan priests or because their boundaries had changed during the period of observation. For practical purposes, then, the total population was sampled. But in most of the analysis for this paper, I used 131 dioceses (96% of the cases) in which there were no missing data for any variable.

7. Analysis

The major technique of analysis was regression. The strategy was first to trim the number of important variables by regressing resignations on all possible independent variables. The second step was to develop statistically testable networks of variables, given the information from step one and following the restrictions of causal modeling. But the networks could not be simplified to one-directional causation, since I wished to test the consequences of resignations discussed above. And so the third step was to test plausible nonrecursive models; I allowed for feedback from resignations, and used two-stage least-squares (TSLS) procedures to estimate coefficients.

TSLS is a technique to obtain regression coefficients for equations of a non-recursive model, when ordinary least squares is inappropriate. TSLS is useful for static models, in which data are collected at only one time period, but in which quick feedbacks are assumed to occur (Christ, 1966: 432f.; Namboodiri et al., 1975: 513-9). The procedure involves the use of simultaneous equations. (For additional information, see Appendix 1.)

In this analysis, I assumed that all variables drawn from the demographic data source were exogenous, as antecedent in time and relatively stable. The others were thought to be part of an intertwined clergy climate and thus endogenous. Before running the analysis, I tested most of the assumptions necessary for regression and two-stage least-squares analysis (see Appendix 1).

8. Variables

The measurement of all variables, along with reliability and validity scores, where appropriate, are given in Appendix 2. But I will repeat here the measurement of the main variable of interest—priest resignations. As noted, informants reported the number of priests who had resigned in their diocese during the preceding five-year period. Agreement within diocese on this item, as measured by a reliability score of .97, was high. Agreement was also high between these resignation scores and those obtained through official channels by Schoenherr and Greeley (1974). [The Pearsonian r , comparing the two data sets in 55 dioceses, was .91.]

To calculate the diocesan score, I divided the average number of priest resignees, as reported by informants, by the total number of diocesan priests in that diocese for 1966. Thus I created a percentage of diocesan clergy who had resigned the ministry during the five years.

FINDINGS

1. Antecedents

As predicted, many structural conditions appeared to influence diocesan res-

Table 2. Stepwise Regression of Priest Resignations on All Possible Structural Influences

* Control variables included summary diocesan scores for possible bias due to position, age, religious liberalism, absence, and disagreement among informants.

ignation rates. Nine of 17 postulated influences had statistically significant regression coefficients at .05 (see Table 2). As expected, episcopal policies made some difference, as negative sanctions and clergy autonomy appeared to promote resignations. Also as expected, the informal clergy climate was apparently influential: priest passivity and dissident solidarity seemed to trigger resignations. Finally, environment and formal structure were quite important. As expected, the percent of parishes staffed by religious clergy, regional supremacy, duration of assistantship, and priests in nonparish work all appeared to promote resignations; size of Catholic population appeared to prevent resignations. Only one of these relations was in the direction opposite to that predicted—clergy autonomy.

The pattern of relationships, however, was not as predicted. The greatest portion of the variance (23%) was explained by environment and formal structure; while episcopal policies explained only a small fraction (3%) and clergy climate explained a modest amount (13%). This is especially remarkable by contrast with a model explaining priest protest.

The following comparative data, taken

from a companion analysis using identical variables² to explain both resignations and priest protest, are illuminating. Episcopal policy and clergy climate accounted for 49% of the explained variance of priest protest, but only 7% of the explained variance of resignation rates. Variables of environment and formal bureaucratic structure accounted for only 5% of the variance of priest protest, but 25% of the variance of resignation rates. Clearly the authority relations and informal climate among bishop and clergy were much more important in triggering protest than in causing resignations. On the other hand, environment and formal structure were more salient in triggering priest resignations.

Finally, the greatest impact on resignations seemed to come from variables I classified as facilitators rather than causes. True, four of the significant regression coefficients reflected causes drawn from constitutive theories. But

² In order to use identical variables, two variables that were not theoretically appropriate for the analysis of conflict had to be dropped, though they were used in Table 2. They were estimated clergy passivity and estimated degree of priest protest. As a result, explained variance figures reported in this textual paragraph differ to some extent from those given in the preceding paragraph.

three of the four most strongly related variables—i.e., each accounting for more than 2% of the variance of resignations—were classed as facilitators. These were: staffing by religious clergy, percent Catholic population, and regional dominance; they explained 20% of the variance, compared with 10% explained by the fourth, probably a causal variable—clergy passivity.

2. Consequences

Consequences of resignations could not be tested in such a straightforward way, due to the strictures of feedback models (see Appendix 1, #4). And so I organized the variables into a network of endogenous variables (episcopal policies and clergy climate), influenced by exogenous variables (all others). As mentioned above, exogenous variables were relatively stable variables, obtained from the demographic source and dating from 1966, the beginning of the period of observation. These were assumed to be only antecedents and not consequences.

I then tested the theoretical model mentioned earlier, incorporating the findings displayed in Table 2 and trying the feedback of several variables within the endogenous set. I especially tested the plausible consequence of priest resignations on all other endogenous variables. Using two-stage least-squares techniques, I eventually found the best fitting and most parsimonious empirical model, which is displayed in Figure 1 and tabulated in Table 3. Note that variables which were not empirically part of the causal network are omitted.

Priest resignations had no discernible impact on any of the endogenous variables. In fact, the only feedback that appeared in the findings was the negative influence of ideological polarization (X_3) on democratic leadership of the bishop (X_1). This finding is in line with predicted conservative tendencies of bishops, when clergy become too liberal for them, since the polarization measured was that between bishop and more progressive clergy. But the data lend no support for a retrenchment caused by resignations themselves. They also do not support the

other expected result of resignations, namely, a betterment of the informal clergy climate.

By contrast, episcopal policies apparently turned conservative in reaction to priest-initiated conflict aimed at bishops. As shown in Table 4, the impact of such priest rebellion was thorough, according to the causal analysis. Direct impact apparently occurred on episcopal leadership and use of sanctions, both of which showed a tightening of the reins of leadership—restricting democracy and employing more negative sanctions. In addition, priest protest seemed directly to enhance solidarity among dissident clergy. Indirectly, too, priest-initiated conflict, reducing clergy autonomy and cross-status friendships, and increasing ideological polarization, influenced other aspects of the clergy climate.

3. Models of the Church

The above findings reflect the operation of models of the church along the lines I expected, but with major modifications. As expected, there was a degree of local *episcopal* autonomy, reflected in substantial variation in the following factors: democratic leadership, progressivism of bishop, negative sanctions, clergy autonomy. Mean standard deviation of these variables, standardized for comparison,³ was 1.61 which was high in comparison with all other variables. If we judge by informal comments at the end of questionnaires, dioceses ranged from extremely progressive to extremely reactionary. And all of this was clearly understood by the local clergy as a reflection of the particular bishop. In this sense, then, the Catholic church of that era was not completely monophasic, but somewhat pluralistic or polyphasic.

Second, the transition from an autocratic to a more democratic style of leader-

³ Standard deviations were standardized by dividing by the possible range and multiplying by ten. An example of smaller variation occurred in the "error" or control variables, whose variation had been consciously minimized by the research design. They showed a mean standardized standard deviation of .68 (see Seidler, 1974c:828).

	Clergy passivity	1.071	1.466	.10	.080	.446

Notes: This represents a trimmed model, with nonsignificant variables omitted. N = 131.

* Since the noncursive program did not print added R² for each variable, added R² was computed by running several equations starting with control variables and adding one significant explanatory variable to the equation in each subsequent run. R² was the R² for the equation which had that variable minus the R² for the preceding equation.

** Control variables included summary diocesan scores for position bias, age bias, religious liberalism bias, absence bias, and residual disagreement among informants.

ship at the local level seemed to have become an *idealized norm*. Clergy who acted as informants for this survey—all of whom occupied a position of responsibility in the diocese—judged themselves as substantially more progressive than bishops. And the most common written complaint was

that the bishop acted in an arbitrary and nondemocratic style.

But several modifications need to be made, and all of them rest on a distinction between two different issues: diocesan harmony and clergy commitment. In general, the expected models applied when

Table 4. A Comparison of the Impact of Priest Protest and Resignations on Episcopal Policies and Clergy Climate

Dependent Variable	Independent Variable

* Asterisk indicates significant indirect impact, through other variables.

the issue was harmony but not when the issue was clergy commitment.

The first modification is that style of home rule was only partially important. Although episcopal leadership was an important determinant and consequent of priest protest, it appeared to be neither a strong antecedent nor consequent of clergy resignations. More important than local pluralism or home rule were the local environment, staffing, and bureaucratic structures.

Second, democratic structures seemed only partially important. Although clergy harmony seemed to depend heavily on the degree to which the local diocese incorporated emerging ideals of democracy, service orientation, and informal solidarity, these seemed less important for clergy commitment. Instead, structural facilitators or opportunity were more salient.

Third, the diocese thus operated only partially as a closed system. Authority relations and clergy climate operated as a rather complete system, impervious to outside influences, when the issue was harmony. But in the case of resignations, this system was not able to contain important influences, as resignations were triggered by outside factors.

Finally, the lack of feedback from resignations, combined with the conservative reaction to protest, apparently indicated a lack of sensitivity by authority figures to professionals and their grievances. We can surmise that such lack of sensitivity may have produced a cynicism about church authority. In addition, bishops and their advisors showed a lack of interest in competition. Whereas they reacted negatively where priest protest was in high gear, they simply let priests with decreasing commitment move to another occupation or market.

THE LAZY MONOPOLY

The lazy monopoly may serve as a useful concept in understanding American Catholic dioceses of that era. Adapted from Hirschman (1970), it is a complex model which incorporates aspects of environment, leadership, exiting, and feedback from exiting.

The criteria for applying this concept (Hirschman, 1970:57-75) can be generalized as follows: (1) The organization is a virtual monopoly—i.e., has singular control over a resource or product. (2) Executives are slow to improve the quality of product, policies, or the structure of the organization. (3) Executives, rather than improving quality, prefer to lose clients or personnel who exercise voice (criticism). (4) They welcome opportunities for critics to exit, often via limited competition. (5) These opportunities allow the continuation of status quo policies or mediocre leadership, as a loss of critics reduces the pressure for change and usually leaves the remnant on the conservative or uninvolved side.

In economic writing, the lazy monopoly had been introduced in French research and briefly noted in Anglo-Saxon literature (Hirschman, 1970:57-8). Albert Hirschman (1970: chaps. 5-6), wishing to underscore a neglected problem of monopolies, refined the notion. Besides the frequently mentioned exploitation and profiteering that can result from the profit-maximizing tendency, monopolies also indulge in the nearly opposite tendency to become flabby, inefficient, and lazy (Hirschman, 1970: 57). The outcome is described as follows:

The monopolist sets a high price for his product, not to amass super-profits, but because he is unable to keep his costs down; or, more typically, he allows the quality of the product or service he sells to deteriorate without gaining any pecuniary advantage in the process. (Hirschman, 1970:57)

Examples cited by Hirschman include utilities, railways, and the Post Office.

The strategy of lazy monopolies apparently consists of developing a product that is adequate for most clients, consumers, or members, but not equal to the standards of their most quality-conscious customers or personnel. Imagining a continuum with quality products drawing only praise at one end and low quality items drawing complaints at the other, executives of lazy monopolies choose a point in the middle range of the continuum. Thus they develop a product to reap adequate profits while losing critical clients. Such a tactic is that of a lazy person—pleasing

mediocre tastes and satisfying those who seek no changes.

Lazy monopolies ironically find comfort in competition (Hirschman, 1970: chap. 5). Minor competition can syphon off clients or members who most strongly demand quality performance. Given the opportunity for such clients or members to exit in favor of another company, the monopoly can remain in its mediocrity. According to Hirschman (1970:59) this applies "to small city or 'ghetto' stores which lose their quality-conscious patrons to better stores elsewhere." It also applies "to sluggish electric power utilities in developing countries whose more demanding customers will decide that they can no longer afford the periodic breakdowns and will move out or install their own independent power supply" (Hirschman, 1970:59). Hirschman also calls the U.S. Post Office a lazy monopoly thriving on limited exit possibilities, via telegraph and telephone, for those who can afford faster communication (Hirschman, 1970:60). Limited competition, or exit possibilities, make the shortcomings of mail service more tolerable. They also may allow such monopolies to "tyrannize" customers who cannot afford swifter forms of communication. Through such monopoly-tyrannies, the incompetent oppress the weak and the lazy exploit the poor (Hirschman, 1970:59-60).

Hirschman also uses political examples to show how exit possibilities rid lazy monopolies of voice (i.e., criticism). In Latin America, power holders traditionally encourage political opponents to move out of the country in voluntary exile. Columbian law provided that former Presidents be paid more handsomely if they lived abroad than if they remained in their own country (Hirschman, 1970:60-1). By contrast Japan has maintained a no-exit policy and the result has been a considerably more vigorous and constructive political process, based on the necessity of compromise. On the other hand, the Latin American exit policy has contributed to the factionalism and *personalismo* characteristic of their politics (Hirschman, 1970:61).

Other examples of lazy monopolies come to mind. Repair shops of car deal-

erships are notoriously careless and overpriced. As monopolies of a sort, they have more than enough business and can afford to be lazy. In fact, they often appear not to want a customer's business, especially if the customer is critical, and they thrive on the exit possibilities provided by nonaffiliated repair operations. In some states, public universities dominate higher education. As lazy monopolies, they often allow mediocrity in teaching while supporting research activities. They take comfort in limited competition from liberal arts colleges, which draw many who would demand high quality teaching.

THE CHURCH AS LAZY MONOPOLY

First, Catholic dioceses were monopolies. They maintained unique control over the opportunities of priestly ministry and organization of life for those ordained as diocesan priests. Dioceses effectively offered the sole opportunity for diocesan priests to continue serving, unless they wished, as extremely few did, to return to a noviceship and a new training in a religious order. And even if they decided to switch authority structures by joining a religious order, they would remain ultimately under the same bishop's jurisdiction if they wished to continue working in that locale. In addition, the opportunity to relocate in another diocese was not freely given. In my data, an average of only 1.4% of diocesan priests per diocese relocated to another diocese during the five-year period. Finally, only a very few priests, often in well-publicized episodes, chose to change denominations and continue as ministers in a Protestant church. But such an alternative was psychologically unlikely for those in a church that remained rather exclusive despite recent ecumenical gestures.

Second, Catholic bishops of the late 1960s were slow to improve the quality of structure or seriously to address fundamental issues. As shown above, increased resignation rates—a sign of a basic problem in clergy life—did not trigger changes in episcopal policy or clergy relations, at least for that period. Even vocal and other direct criticisms did not produce policy changes, except in the more conservative

direction. Since these criticisms came from a more liberal clergy and were aimed at an overwhelmingly moderate set of bishops (NORC, 1972; Seidler, 1972), such reaction to the right could not be considered an improvement in basic issues. At that time, lower clergy still complained in large proportions about the lack of such administrative procedures as due process, grievance mechanisms, and personnel assignments (Fichter, 1968; Seidler, 1974a; 1974b). It was not until the last year of investigation for this research that each diocese, by decree from Rome, set up a priests' senate, giving at least formal representation to lower clergy in the diocesan decision-making process, though these senates lacked real legislative power. Overall, then, bishops did not deal with fundamental clergy problems, since they dealt with neither explicit conflict nor resignations as legitimate feedback.

Third, the reaction of bishops and diocesan administrators appears to have been, "Let the troublemakers go." Indirect evidence points strongly in this direction. In the present data, Ordinaries made no conciliatory changes in the wake of priest resignations. And we know that those exiters were, on the whole, more liberal than stayers (NORC, 1972). Thus they would most likely have viewpoints in opposition to bishops. In addition, those who resigned often did so after suffering penalties resulting from confrontations with diocesan administrators, usually bishops.⁴ Furthermore, priest resignations frequently were publicized by church officials as the departures of disloyal clergy. Therefore, the lack of policy reaction to departures probably reflects an episcopal attitude of relief at such departures.

Fourth, bishops apparently welcomed the opportunities for exiting, when priests

wished to resign. Clearly bishops did not stop the resignations. And clearly the variation in resignation rates was largely explained by opportunities or facilitating conditions. For example, regional dominance, indicating bureaucratic centralization, probably eased the paper work of exiting. Priests in nonparish work—indicating full-time assignments of clergy to educational, counseling, or administrative tasks—probably eased the transfer to parallel nonpriestly roles. Percent of parishes run by religious clergy possibly indicated a knowledge of resignation procedures, and a desire to imitate other resignees, since the exiting rates of religious clergy were higher at that time (NORC, 1972:278). Finally small Catholic populations apparently minimized religious pressure to remain. Such social factors eased the transition of resigning priests to the competition—i.e., a nonpriestly career. They also apparently gave bishops the welcomed chance to neglect structural shortcomings by watching the most dissatisfied clergy depart.

Fifth, bishops maintained a status-quo policy—i.e., no change—as an outcome of resignations. In addition, they moved in a conservative direction in reaction to the simultaneous problem of clergy conflict, as noted above. Again, since conflict was initiated mainly by more liberal clergy, this tactic, combined with the lack of reaction to priest resignations, shows that bishops considered neither protest nor departure a legitimate form of criticism. Rather, exiting was no doubt a release from the need to move ahead.

Therefore, American dioceses can be described as lazy monopolies during that era, as their actions were parallel to those of officers of nonreligious lazy monopolies, who allow disgruntled clients to retreat from their own product to something else rather than deal with basic issues. Variations, of course, existed in the degree to which each diocesan monopoly was lazy, but the general pattern seems to have fit this model.

International Catholicism also could be labelled a lazy monopoly. First, it was a monopoly because all western Catholic clergy remained under the jurisdiction of Rome. Though within limits bishops could

⁴ In some cases, such as that of William DuBay of Los Angeles, both protest and resignation were dramatic and highly publicized. In others, the connection between protest and resignations was not so well-known. For example, the protest by priests in Washington over that bishop's stand on the papal decree on birth control was well publicized, but the subsequent resignation by many of them, after being silenced and stripped of responsibilities, was only widely disseminated in the local ecclesiastical grapevine.

set local conditions for clergy, the Vatican still controlled basic rules of priestly life. In addition, the worldwide Catholic monopoly became exceptionally salient for clergy during that era. The Vatican Council (1962–1965) drew great attention to the new spirit initiated in Rome and dependent not only upon Council documents but also upon follow-up actions by the Vatican. Indeed, the pope's appeals to prudence and gradualism clearly set a restraining tone to diocesan progress, and rising and frustrated expectations of diocesan clergy clearly were associated with Vatican impulses.

Second, international Catholicism was hesitant to come to grips with fundamental issues, even while undergoing modifications introduced at the Vatican Council. For example, the Vatican held firm to its celibacy ruling for priests, though the desire to marry was a crucial element in the decision of American priests to resign (Schoenherr and Greeley, 1974), and though recent research has shown the arbitrariness of the celibacy law. In addition, the Vatican bureaucracy only slightly tempered its structure, though a basic overhaul was considered of utmost importance, and most decrees of universal change concerned matters of style or presentation, rather than basic normative or structural matters (Davis, 1967:13–4).

Third, international Catholicism was happy to be rid of troublemakers. Here, the process of official resignation is enlightening. Clergy who desired to resign made written application by using a few officially acceptable reasons for asking release of vows. These reasons effectively defined the person as deviant. Others, electing to marry first without official approval quickly were released from the clergy ranks.⁵ Thus "misfits" were gladly sent off, while the purity of hierarchy officially was preserved.

Fourth, the Vatican allowed opportunities for "deviants" to exit. Deviant definitions clearly were broadened to cope

with the increased volume of requests for resignations, and thus to allow greater opportunity for exiting. Thus the Vatican readily granted permission for those defined as deviant to depart.

Fifth, international Catholicism essentially maintained the status quo and apparently appeased the loyal conservatives. Pope Paul is generally thought to have catered to the conservative Vatican bureaucracy in doctrine and discipline, even while promoting the spirit of Vatican II in symbolic ways. In addition, his reign brought a slowing of the Council bandwagon, which was perceived by many as a turn to the right.

DISCUSSION

1. Monopolies in the Wider Religious Scene

Roman Catholicism has no doubt changed its form of monopoly. In earlier decades, when it disallowed clergy resignations and criticism, it might have been named a totalitarian monopoly. But the winds of change, legitimated at the Vatican Council, apparently initiated a new organizational strategy. Church officials, enmeshed in the ecclesiastical establishment, could maintain conservative policies and a slow pace of change, in the face of strong progressive trends, by taking the shape of a lazy monopoly. Such a strategy, which may have lasted but a few brief years, seems worthy of note.

Other denominations also can be considered monopolies, whether lazy, totalitarian, or profit-maximizing. In many nations, including traditional Europe and Latin America, religious denominations long have monopolized a geographic region. And even today, despite the influx of American-based sects and increasing religious competition, many European countries (or specific regions within countries) maintain essentially monopolistic religions which allow minimal competition. Similarly in the United States, indications of Mormon territory, Baptist country, or Jewish ghettos perhaps reflect local monopolies within a broader context of religious pluralism.

Monopolies also can develop out of competitive situations. For example,

⁵ This information is known both from personal experience in dealing with the Vatican, and from informal sources—mainly a variety of friends who went through the resignation process or who counseled those desiring it.

though Protestantism apparently maintains a tradition of competition and religious freedom, reflected in current denominational switching (Roof et al., 1977), regionally monopolistic denominations thrived in early American colonies. More contemporary groups, too, have attempted to establish themselves as monopolies, though they began in the competitive market. Reverend James Jones apparently sought, through the People's Temple in Guyana, to create a tyrannical monopoly over his segment of the population—a tyranny in which both voice and exit were stifled. Other groups, such as the Unification church, also curtail the development of voice and exit, while creating an ideology that would support a future monopolistic role in society.

2. *Relation to Other Research*

As noted at the outset of this paper, the research reported here is related intricately to past studies of priest resignations, clergy climate, and other pertinent events of the same time period. The relationship between this research and those investigations can be summarized as follows; I have divided the findings reported here into those that are new, those that converge with other studies, and those that provoke new questions.

A. *New aspects.* New elements of this research include the lazy monopoly model, the test of short-run feedback, and significant structural effects on priest resignations. The last item requires further elaboration.

Other researchers have not discovered the statistical impact of structural factors on priest resignations, despite research on other occupations that shows the effects of such contextual influence as routinization and promotional opportunity (Price, 1977). True, Hall and Schneider (1973) found contextual sources of work dissatisfaction and tension among priests, but they did not explicitly examine resignations. More pointedly, Schoenherr and Greeley (1974), investigating aggregate and contextual sources of resignations, found practically no structural effects—only a slight effect from the aver-

age resignation rate itself, i.e., the "cumulative impact of many priests in the diocese planning to resign" (Schoenherr and Greeley, 1974:421). In fact, they concluded that, "aside from important but rare exceptions, higher level social influences are too remote and too dispersed to affect strongly a priest's personal decision to continue" (Schoenherr and Greeley, 1974:421-2).

Several factors may explain the discrepancies between their findings and mine. First, Schoenherr and Greeley omitted the five structural variables which in this study produced a significant impact on resignations. Perhaps their inclusion of organizational variables producing psychological inducement or cost (Schoenherr and Greeley, 1974: 418-9) led them to overlook apparently nonpertinent sources of resignations. Yet they did test a battery of variables, and their theory was broad. Nevertheless, the significant structural sources of resignations in this study were, as a matter of fact, unique.

Second, Schoenherr and Greeley (1974: 420-1) attempted to find structural effects, largely *in addition* to individual (or social psychological) effects, whereas I attempted to obtain structural effects *only*. Granted that in their study zero-order correlations between group-level and individual-level variables, including resignations, were very low (Schoenherr and Greeley, 1974:420), the impact of group-level factors might have been masked when attempting to explain additional influence on individual-level outcomes. Individual-level variables may partially usurp the explanatory power of contextual variables, especially when the contextual variables (e.g., average resignation rate) consist of the same items aggregated to the group level. If so, this may account for generally disappointing results of contextual variables in regression analysis (Blalock, 1969).

Third, Schoenherr and Greeley's path model implies structural influences, even though the variables are framed at the individual level. For example, in their model, modern values induce work dissatisfaction and a desire to resign, regardless of the motivation to marry (Schoenherr and Greeley, 1974:415). But

such sequences only make sense if the work climate or structure is regulated by traditional values. Modern values obviously imply new desires for the exercise of authority, job specifications, rules, and other matters, which go against prevailing structures, thus causing dissatisfaction.

Finally, the most unique element of structural findings presented here is the impact of facilitating variables on resignations. The element considered most theoretically pertinent—the route through passivity—finds continuity with Schoenherr and Greeley (1974) and Schallert and Kelley (1970), even though both their studies are primarily social psychological. We now turn to that continuity.

B. Convergent aspects. A general deprivation theme runs through the research on priest resignations. Schallert and Kelley (1970), in their qualitative study, stated that change-oriented clergy resigned because of alienation, the retention of traditional ecclesiastical structures, and a slow church evolution toward modern values. Such variables reflect a cramped (or deprived) professional climate. Schoenherr and Greeley (1974), in several diagrammed "routes" to resignations, displayed the following influences on the decision to leave: inner-directedness, modern values, work dissatisfaction, and loneliness. These factors also indicate deprivation of a satisfactory work or life climate.

Threads of continuity among these three studies, including the one presented here, are many, whether they be viewed from a psychological or structural standpoint. They include a gap between lower clergy and hierarchy, professional autonomy (or inner-directedness), modernization (or progressivism or change-orientation), social support (or loneliness), and work satisfaction (or passivity or alienation). This deprivation constellation can be considered one route to resignations.

A second parallel in all three studies is the *partial* explanatory role of the common deprivation constellation. The other investigators put heavy emphasis on an additional factor—desire to marry (Schoenherr and Greeley, 1974) or a let-

down by a significant other (Schallert and Kelley, 1970). In this study, facilitating factors come strongly into play.

In addition, results of this study converge with data on general job turnover. Leaving one's job has been associated with dissatisfaction, professionalism, and various work conditions, including centralization and lack of social integration (Price, 1977). Such conditions roughly parallel the deprivation constellation described here.

Job turnover also has been associated with the possession of transferable skills and opportunities to go elsewhere (Price, 1977), and these conditions roughly correspond to facilitating conditions as presented here.

C. Open questions. Questions naturally are raised about important variables from other research not treated in the present study. For example, how are these findings related to the strong relationship between resignations and the desire to marry (Schoenherr and Greeley, 1974)? In partial response, I will make three comments.

First, since priestly marriage is not a local option, the desire to marry does not translate to a diocesan policy issue. It is therefore not a diocesan-level cause of resignations, and it clearly does not fit the present model.

Second, however, the very irrelevance of the celibacy issue at the diocesan level may help explain why facilitating factors were more salient than causative factors. If indeed the desire to marry exercises a strong and independent pull toward resignations at the individual, but not diocesan, level, the analyst would expect causative diocesan influences to be weak.

Third, the lazy monopoly concept may be complementary to the finding about the desire to marry. This paper has argued that lazy monopolies are insensitive to constructive criticism. Following this line of reasoning, the Catholic hierarchy will not have answered fully the criticism of liberals until the Vatican changes its celibacy rule.

Another open question regards the relationship between this study and cynical knowledge (Goldner et al., 1977). Cynical knowledge, a basis for priest decommitment (Goldner et al., 1977), is said to have

developed during recent decades when Catholics became aware that hierarchical decisions were dictated by political and organizational considerations, rather than pure altruism. How does this explanation relate to findings presented here?

The cynical knowledge theory is distinctive in placing major explanatory emphasis on the manner in which lower participants perceive actions of officials. By contrast, the deprivation approach, including the causative element in the present research, underscores the effects of official actions—i.e., the conditions of work and life for lower participants.

Perhaps cynical knowledge and deprivation vary together on occasion. For example, cynical knowledge among diocesan clergy may emerge in those places where bishops are thought to resist modernization *because* of political or selfish considerations. On the other hand, perhaps disillusionment arises from deprivation or cynical knowledge operating separately.

Finally, cynical knowledge theory implies that church officials attempt to maximize personal or political gain. But the lazy monopoly theory suggests that the hierarchy, in its unwillingness to face such issues as celibacy, often may seek only an adequate, nonoptimum solution. In either case priest commitment may be lessened.

Questions obviously remain for future research. Which influences are more important for clergy commitment: the perception of a political and selfish hierarchy, or the alienation, passivity, and loneliness resulting from hierarchical decisions and experienced by clergy? Do we need a multi-source explanation, or does a single type of explanation suffice? And which kind of monopoly brings on higher resignation rates, the profit-maximizing monopoly or the lazy monopoly?

Turning directly to monopolies, researchers may ask under what conditions organizations tend towards monopolistic practices? In particular, when do they become lazy, rather than tyrannizing or profit-maximizing?

Finally, additional studies are needed to discover if the lazy monopoly applies to

church actions at other time periods, or only for this single "moment" in church history. Since 1971, structural innovations, such as diocesan pastoral councils, pastoral planning commissions, priests' senates, and personnel boards—but not optional celibacy—have been widely institutionalized in the United States. Perhaps these new structures were instituted because of the increased resignation rates. If so, the church may have begun to perceive the competition from attractive nonreligious career patterns to have gained strength, thereby challenging the monopolistic hold of the church on priests' lives. For it is only when the competition is weak that lazy monopolies are operative (Hirschman, 1970:57ff).

APPENDIX 1

ADDITIONAL DETAILS OF METHODOLOGY

1. *Preliminary investigation.* At first, about 15 structural positions, besides pastor and assistant pastor, seemed plausible informant positions, since they existed in most dioceses. But I suspected that they represented different branches of the information-grapevine and varying biasing pressures. I thus decided to investigate the degree of knowledge and bias I could expect from people occupying these positions by virtue of the structural slots themselves.

I sent questionnaires to 51 Catholic sociologists, particularly those specializing in the study of Catholicism. The 27 who completed questionnaires rated each position on expected bias and knowledge of clergy-bishop relations. Focusing on the reportage of tensions between bishop and lower-level clergy, they estimated extent and direction of expected bias, whether in favor of bishop or lower-level clergy. From the summarized ratings, I chose ten positions according to the following guidelines:

- (a) Only those with moderate to high degrees of expected knowledge were chosen.
- (b) As many as possible were chosen from the middle range of expected bias—i.e., those predicted to be relatively unbiased.
- (c) Positions expected to produce the greatest bias were eliminated. For example, the chancellor was eliminated because he was expected to be most biased in favor of the bishop.
- (d) A relatively balanced set of positions was chosen by selecting a few from each side of the bias continuum after all positions judged to be relatively objective had been included. The final set of ten ranged, thus, from those expected to be protective of the bishop (e.g., Dean or Vicar) to those expected to be critical of him (e.g., member of Priests' Senate or Council).

Weightings of the responses were not considered necessary, because biases were expected to balance. In addition, I created several control variables which

represented possible sources of bias, and these were expected to screen out error during the analysis itself.

The positions chosen were not always occupied in every diocese, nor was every diocese sufficiently differentiated to have every position. Thus, though ten positions were contacted in most dioceses, some dioceses received fewer than ten questionnaires. But six or more positions were always contacted. Even so, an average of seven questionnaires was completed in each diocese.

2. *Reliability and validity.* To test agreement of informants within each diocese, I adapted the split-half reliability formula to these data. After dividing informants in half for each unit of analysis, I obtained the correlation between mean scores of each half in all dioceses for a particular item. This correlation formed the basis for computing the split-half reliability coefficient. As mentioned above, average reliability across a subsample of eight questionnaire items was .8.

Of course, this was an imperfect adaptation of the split-half reliability formula. Informant halves often were imbalanced in expected bias, especially in those dioceses where the return rate was higher on one side of the bias continuum. In addition the mere splitting of a small sample (ten or fewer) increases the appearance of disagreement by creating two very small units which are likely to have different means. Hence the overall reliability coefficient is probably a low and conservative estimate of informant agreement.

Concurrent validity (see Kerlinger, 1965:447ff.) was examined by comparing a few items with information obtained in other studies or reports. Where similar data were collected by Greeley and Schoenherr (NORC, 1972), my findings coincided with theirs. As mentioned in the main text, a correlation of .91 was found between the two matched sets of 55 diocesan resignation scores for 1966-1970—one obtained by informants in this study and the other provided by official records in the Schoenherr-Greeley study (1974). In addition, total resignation percentages in the United States for those five years were similar, though computed differently. In my data the total was a weighted average of diocesan scores; in the Schoenherr-Greeley data, I extrapolated to the five years by adding the average yearly increment they discovered in the four-year period of observation. Results were 6.34% in my data and 6.1% in their data.

Other items, such as conflict events between bishops and clergy, were checked against newspaper accounts, and in a selected handful of dioceses, the exact events reported in the press also were recalled and reported by my informants.

3. *Analysis.* Since regression was the primary mode of analysis, I examined the appropriate assumptions, including linearity, homoscedasticity, and skewness. All were found to be within acceptable ranges, especially after two variables (diocesan size and teaching corps) were given a log transformation because of excessive skewness. All of the exogenous variables and one endogenous variable (percent resignations) formed interval scales. The rest were ordinal, having been derived from items

with five to seven fixed response categories, yet that had the appearance of interval scales after the averaging operation. Interval statistics were employed.

In developing causal networks, I placed variables in sequence according to theoretical considerations, previous research, and personal judgment. Where feedback was incorporated, it was assumed to be a quick adjustment, rather than a gradual or long range effect, in keeping with the nature of cross-sectional data and the assumption of two-stage least-squares analysis.

Since the model included two-directional causal paths, two-stage least-squares procedures were followed to estimate coefficients. Seven equations were composed for each stage, and the structural equations were all exactly identified or overidentified, leaving out at least $k-1$ variables from each equation (where k = the number of endogenous variables).

Multicollinearity problems were diminished by ruling out any independent variable that was correlated with another at $\geq .85$ (Althauser, 1971:453). Although a degree of multicollinearity probably persisted, findings turned out to be consistent, whether basic models were run with or without several substantially correlated variables. Hence findings reported here apparently represent the sense of the data.

All equations employed special control variables to screen out possible effects of measurement error. Such control variables included summary diocesan scores for position bias, religious liberalism bias, the extent of intradiocesan informant disagreement, and others (see Seidler, 1974c).

4. *Two-stage least-squares analysis.* Two-stage least squares (TSLS) is a technique to obtain regression coefficients for equations of a static but non-recursive model, in which the causal flow cannot be assumed to be one-directional or in which quick feedback is assumed. Since, in such situations, ordinary least squares would yield biased and inconsistent estimates of coefficients, an alternative, such as TSLS is required. The problem with ordinary least squares is that the error terms of individual equations cannot be considered independent of the endogenous variables that appear in the same equation as independent variables.

To solve this problem, we put equations in "reduced form"; only exogenous variables are used as independent variables. Thus the values of endogenous variables are predicted jointly by all (and only) exogenous variables (here: the control variables mentioned above, and $Z_1 - Z_n$). Then these predicted values are substituted for all endogenous variables *when they are acting as independent variables*. Their predicted values, in addition to observed values of pertinent exogenous variables, then, are used to compute a set of coefficients for each equation.

This procedure assures that the resultant error terms will be uncorrelated with the independent variables of each equation, so long as the exogenous variables are truly exogenous. This, of course, implies that they are uncorrelated with disturbances. Under the assumptions that each equation is identified, and that there are no specification or measurement errors, two-stage least-squares techniques

will produce consistent coefficients with negligible large-sample biases (see Christ, 1966: 432f).

APPENDIX 2

OPERATIONALIZATION OF VARIABLES

Z₁ Urban Concentration: proportion of parishes in towns or cities of greater than 10,000 population.

Z₂ Percent Catholic Population: percentage of Catholics in the population of the area.

Z₃ Diocesan Size (log): absolute number of Catholics in the diocese.

Z₄ Regional Dominance: status of diocese as province headquarters, i.e., administrative center for several dioceses in a region (scored 1 or 0).

Z₅ Priests per Parish: average number of diocesan priests per parish run by diocesan clergy.

Z₆ Duration of Assistantship: average number of years a priest remains as assistant pastor before being promoted to pastor.

Z₇ Staffing by Religious Clergy: percentage of parishes run by religious clergy (i.e., those subject to superiors of religious orders, and not primarily under a bishop; instead under a jurisdiction whose area is much broader than a diocese).

Z₈ Teaching Corps (log): absolute number of priests engaged full-time in teaching. (The absolute number, rather than a percentage, was chosen because it was thought that a critical mass for unrest could be achieved by a sizable group of scrutinizing academics, whatever their percentage of membership.)

Z₉ Priests in Nonparish Work: percentage of diocesan clergy engaged full-time in nonparish work.

X₁ Democratic Leadership of Bishop: a four-item scale, including informant estimates of the following: willingness to hear grievances, encouraging the participation of all priests in decision-making processes of diocese, desire for the diocese to serve all people, both inside and outside the church, and overall leadership. Reliability (Ω) was .90; validity (P_{TS}) was .95. (For measures, see Heise and Bohrnstedt, 1970.) In this model, democratic leadership (X_1) can be conceived of as representing, besides the items contained in that construct, a progressive attitude toward change. Such progressivism was highly correlated with democratic leadership ($r=.73$). Its inclusion led to empirical results which generally said identical things about democratic and progressive leadership. Therefore, progressivism of bishop was dropped from this analysis.

X₂ Clergy Autonomy: estimated degree of autonomy enjoyed by diocesan priests.

X₃ Ideological Polarization: a three-item scale, giving an estimated percentage of diocesan clergy who disagreed with the bishop by thinking more progressively. The issues concerned the importance of guarding doctrine, enlarging church membership, and supporting humanitarian concerns. Reliability (Ω) was .84; validity (P_{TS}) was .92.

X₄ Cross-Status Friendships: a three-item scale, giving estimated degree of communication and friendship between pastors and head bishop, between assistant pastors and bishop, and between diocesan administrators and the rest of diocesan

clergy. Reliability (Ω) was .88; validity (P_{TS}) was .94.

X₅ Negative Sanctions: estimated frequency by which the bishop punished his diocesan priests by undesirable transfers, calling on carpet, and so forth.

X₆ Priest Protest: estimated degree of dissent or opposition expressed by diocesan priests in reference to their chief bishop.

X₇ Dissident Solidarity: estimated degree of camaraderie among diocesan priests who dissented with the chief bishop.

X₈ Clergy Passivity: estimated percentage of diocesan clergy who were passive because disillusioned about the possibilities for a happy and effective ministry within the diocese.

X₉ Priest Resignations: percentage of diocesan clergy who resigned the ministry—calculated by averaging the number of priests in a particular diocese who, as recalled by informants, had resigned in the previous five years, and dividing by the total number of diocesan priests in that diocese for 1966.

EARLY CHILDBEARING AND LATER ECONOMIC WELL-BEING*

SANDRA L. HOFFERTH

KRISTIN A. MOORE

The Urban Institute

American Sociological Review 1979, Vol. 44 (October):784-815

Early childbearing has been assumed to result in numerous social and economic problems, including school drop-out, large families, and poverty. However, few studies have been conducted within a multivariate, nonrecursive framework, and researchers have not traced the causal and cumulative effects of an early first birth. Using data from the National Longitudinal Surveys of young women on a subsample of women who have borne a child by age 27, we find strong direct effects within a path analytic framework, such that later childbearers complete more education, have smaller families, and work fewer hours at age 27. The relationship with education is recursive among women having a first child by age 18, but simultaneous among later childbearers. Effects of age at first birth on economic well-being at 27 are indirect. Lower education is related to reduced earnings among women and among other household members (usually the husband). Since resources must be divided among more family members, the incidence of poverty is greater. For women who are at least 19 when they have their first birth, the timing of that birth is important to later well-being primarily because of the smaller families and increased work experience of those who postpone their first birth into the twenties. Having an early first birth was found to be less detrimental to the later economic well-being of black women than white women.

The widespread conviction that early childbearing precipitates numerous social and economic problems is founded on surprisingly little evidence. Many associations between teenage pregnancy and lower social and economic attainment have been reported, but the causal role of the occurrence of an early birth has not been established. Researchers have tended to study small groups of girls, typically at only one point in time, and without controlling for important background variables that might affect later status at-

tainment. The possibility that young women who bear children at an early age differ from their childless age peers in numerous ways is often ignored or only mentioned in passing. Therefore, it is not clear whether it is really the early birth or some other antecedent factor that accounts for the social and economic difficulties so often noted among teenage mothers. Furthermore, we lack understanding of the process by which early childbearing might affect attainment. If early childbearing is found to be associated with lower social and economic status after important social, demographic, and motivational variables are controlled, it is necessary to discover the process by which an early birth exerts such a negative impact.

Some of the more sensitive studies that have been done have made it clear that the process is not simple or easy to untangle. For example, Furstenberg (1976) studying a group of teenage mothers over a period of five years, compared them with their high school classmates, some of whom also became premaritally pregnant, some of whom did not, but most of whom are black and relatively disadvantaged. He reports that

their life situations some five years after the birth of their first child reflect a broad range

of advantages and hardships which seem to defy a simple accounting scheme . . . proving how erroneous some of our impressions of early parenthood have been; in particular, the notion that bearing an unplanned child in adolescence leads inevitably to a life of deprivation. (Furstenberg, 1976:xvi)

What, then, is the effect of an early birth—net of social, motivational and demographic factors—on later attainment? Specifically, how do teenage mothers compare at age 27 with young women who postpone their first birth to their early twenties? If they are less well-off, what explanation can researchers provide as to the process? These are the questions addressed in this study of a large, national sample of contemporary young women.

Disadvantages Associated with Early Childbearing

Educators, parents, and policy makers are concerned that premature pregnancy disrupts and accelerates the life course of the adolescent; it preempts the educational, vocational, and social experiences of the teens and early twenties that are so important to later social and economic well-being. As Bacon (1974:333) notes,

any important life event is potentially stress-inducing as one abandons and adopts meaningful social roles. . . . If motherhood occurs very early in life, it is probable that a stress-engendering acceleration of role transitions will lead to . . . social pathologies.

The young mother's first priority must be to secure some means of support for herself and her child, a necessity which could propel her into an unhappy marriage, a low-paying, dead-end job, or onto welfare. Evidence (e.g., Bumpass et al., 1978) also indicates an association between early and rapid subsequent childbearing, suggesting that the young mother may soon find herself with several children to care for. Other evidence suggests that the early childbearer completes considerably less schooling than her later bearing sisters (Furstenberg, 1976; Mott and Shaw, 1978), placing her at a disadvantage on the job market as well as limiting her opportunity for personal and intellectual growth. If she marries, her husband is also likely to be relatively

young and unskilled, so family income is likely to be low (Coombs et al., 1970).

Furthermore, early childbearing pushes a young woman into a role for which she is likely to be only casually prepared. Parenthood is a demanding role even when assumed at an older age (Rossi, 1968). By moving into this role so early, the young woman is immediately set apart from her peers and perhaps estranged from her family as well. Therefore, she may have trouble maintaining a supportive network at a time when her needs for emotional and physical assistance may be especially great.

However, despite the surface plausibility of such arguments, it is also possible that teenagers who bear children differ initially from their later bearing peers; in this case, the occurrence of a birth would only be correlated with later difficulties (or a compounding factor in such difficulties), but not the cause of such problems. Both early pregnancy and eventual poverty might be due instead to lesser motivation, a disadvantaged background, lack of parental encouragement, or to a set of beliefs and values which in themselves lead to lower attainment, regardless of pregnancy.

Are There Possible Advantages to Early Childbearing?

Possible advantages to teenage childbearing should also be considered. Early childbearers may find it possible to "get over with" the childbearing stage and move fairly early into permanent or steady labor force participation, thus contributing to household income and gaining valuable work experience. Young fathers may not obtain as much schooling; but the payoff to a college degree has been questioned of late, given the over-supply of well-educated young workers and the high wages paid in many blue-collar jobs. Among both men and women, work experience has been found to be associated with higher wages (see, for example, Polachek, 1975; Suter and Miller, 1973; Hofferth et al., 1978). Job seniority may reduce the likelihood of unemployment for both men and women. In addition,

working mothers will not be faced with the problems of interrupting work to have a family or of locating child care for preschoolers, as they might if they worked before forming a family; so continuing full-time employment might be more feasible. Finally, although early marriage has been linked to a higher probability of divorce or separation (Bumpass and Sweet, 1972; Norton and Glick, 1976), those couples who remain married may accumulate considerable assets before their peers are even out of school.

Given these possible advantages, it does not seem wise to assume that all of the consequences of early childbearing are negative. Rather, researchers should attempt to sort out positive from negative consequences.

Our research questions are the following:

1. What are the direct and indirect effects, if any, of the age of a woman at first birth on later economic well-being?
2. What are the total effects of the age of a woman at first birth on her economic well-being at age 27?
3. What are the relative sizes of the different indirect effects of an early first birth on later economic well-being? That is, through what intervening variables (e.g., education, family size, labor force participation) does age at first birth have its effects on later well-being?
4. Finally, what are the implications of the empirical results for status attainment researchers and for policy makers?

DATA AND METHODS

The data on which this analysis is based were drawn from the National Longitudinal Surveys of the Labor Market Experiences of Young Women (hereafter referred to as the NLS). The NLS is funded by the U.S. Department of Labor, designed and fielded by the Ohio State University and the U.S. Bureau of the Census. The first wave was fielded in 1968 and sampled 5,159 young women between the ages of 14 and 24. Attempts to reinterview these women were made annually through 1973, with additional, short interviews in 1975 and 1977, plus a complete interview in 1978. Only data through 1975 were

available for the current analysis. Sample retention has been good; by 1975, 82% of the original sample remained intact. Since this survey has been described in detail elsewhere (see Parnes et al., 1971), we will not discuss it further.

Because of the youth and currency of this sample, it is especially relevant for the study of adolescent childbearing in recent cohorts. The longitudinal design allows us to compare women at similar ages without having to depend on retrospective reports, which can be affected by forgetting or selective recall. Furthermore, the data provide information that is both contemporary and rich. Finally, the large sample size provides a sufficiently large pool of individuals for the kind of analysis our hypotheses necessitate.

The design of the NLS has disadvantages as well, since it limits the range of ages of the women sampled, the oldest of whom were only 31 in 1975. Because we wish to examine the effects of early childbearing among a group of women who are all the same age, and whose economic situation is relatively stable, we selected a subsample of young women who turned 27 during the years of the survey, i.e., who were 20 to 24 in 1968, and who had ever had a child.¹ Early childbearers are included in this sample; however, the very late childbearers (beyond age 27) are excluded. Therefore, while we can assess the consequences of early childbearing, we cannot as confidently generalize to late childbearing, since the latest childbearers are not in the sample. To the extent that this latter group differs greatly from the average childbearer, our results are biased. However, the proportion of the sample who had not borne a child was relatively small. Of those 1,791 women who reached 27 during the survey, 87% (1,562 women) had had children.

Missing data present researchers using the NLS with serious problems. Because our interest lay in the relationship be-

¹ Although age 27 is still relatively young, most of these women should be substantially settled. This is not a group of students: 27% had had some college, only 13% had finished, 3% had gone on past college, and 3% were enrolled in school at age 27.

tween a first birth and later economic well-being, those cases in which data were missing on family income when the respondent was 27, the primary component in determining whether or not a family was poor, were discarded.² This group includes nonrespondents as well as respondents for whom data were missing. As a result, 294 cases were eliminated. The remaining 1,268 young women constituted our sample.

Variable definitions, means, and standard deviations are reported in Tables 1 and 2. Variables on which large numbers of cases had missing information were dropped from the analysis. For the remaining variables, means were substituted when information was missing. The proportion of cases for any variable on which substitution was used averaged less than 1%; data were assumed to be missing at random (see Marini, 1979, for a discussion of problems caused by missing data in panel studies and various strategies to deal with such problems).

A second problem was that of young women who had never married. Since we wanted to avoid discarding the never-marrieds, it was necessary to assign an age at first marriage. The 2% who had not married were assigned their age in 1975 (latest year of the survey) plus one year. Prior to recoding, a dummy variable indicating marital status (never-married vs. ever-married) was created, so this information was not lost.

An additional problem is that the NLS data do not contain a childbearing history for the respondent. Consequently, a measure of age at initiation of childbearing created by the NLS staff from the record of persons living in the respondent's household at the time of each survey was used. This means that adopted children cannot be distinguished from the woman's own children. However, research by Bonham (1977) indicates that only 0.5% of all ever-married women under 30 have adopted a child, making this a trivial source of error. Of greater concern is the

lack of information on abortions, stillbirths, and children given up for adoption. This information is, of course, extremely difficult to obtain, and the accuracy of the data is always in some doubt. Moreover, we believe that it is the presence of a child in the home that has such important consequences for the social and economic status of the parents. Therefore, it is actually the age at initiation of childbearing and rearing and its outcomes on which we focus. To explore these outcomes, we developed a non-recursive model of factors resulting from early childbearing using path analytic procedures.

THE MODEL

The dependent variables of primary interest are three: the *respondent's income* at age 27, the *incomes of other family members* (her husband or other family members), and whether or not the respondent's household falls below the *poverty line*, as measured by the Orshansky index.³ These components of household income were chosen as our measures of well-being not only because income affects the food, housing, leisure, medical care, and social status of all household members, but also because poverty places a burden on society as a whole when welfare support is necessary. In addition, household income provides a straightforward and clear-cut measure of well-being.

The factors that we hypothesize to affect the components of household income

³ Poverty is a dichotomous variable coded one if: the household contains one member and income falls at or below \$2,901, the household contains two members and income falls at or below \$3,633, the household contains three members and income falls at or below \$4,319, the household contains four members and income falls at or below \$5,501, the household contains five members and income falls at or below \$6,501, the household contains six members and income falls at or below \$7,319, the household contains seven members and income falls at or below \$9,035; otherwise, poverty equals zero. (Figures for the 1975 income year from the U.S. Department of Health, Education and Welfare, 1976a.)

² Information on household size, the other variable used to determine poverty status, was obtained from the household record; therefore, no data were missing.

Table 1. Definitions, Means, and Standard Deviations of Variables Used in Path Models, Total Sample, Age at First Birth ≤ 18 , and Age at First Birth > 18 ^a

Variable	Definitions	Age at First Birth ≤ 18 N=256		Age at First Birth > 18 N=1012		Total Sample N=1268	
		Mean	Standard Deviation	Mean	Standard Deviation	Mean	Standard Deviation
Age at First Birth	Respondent's Age at the Birth of Her First Child	17.15	1.06	22.42	2.81	21.36	3.32

^b Wages and salary.

^c Business, interest, dividends, unemployment compensation, wages and salary, other.

and poverty, their causal direction, and their temporal order, are diagrammed in Figure 1. Although not drawn in the diagram, the model is hierarchical in that all earlier variables are hypothesized to affect all later variables, with two exceptions: (1) the relationship between age at first birth and education is hypothesized as reciprocal, nonrecursive, and (2) other family income and work experience are assumed to be entered at the same level. That is, neither affects the other, though each affects all later variables.

A number of exogenous variables were available as controls for initial differences and for social, motivational, and demographic influences on endogenous variables in the model. The most important of these are *parental socioeconomic level* and *race*, which have been consistently shown to play important roles in determining later socioeconomic attainment (see, for example, Blau and Duncan, 1967; Duncan et al., 1972; Sewell and Shah, 1967; 1968; Featherman and Hauser, 1976; Treiman and Hauser, 1975) and, we hypothesize, will also be important in determining age at first birth. (Race is included additively in the total sample of respondents; however, the samples are also subdivided by race and the relationship of age at first birth and later economic well-being is explored separately among blacks and whites; see discussion below.)

Although in this analysis we are looking at the economic well-being of all respondents at age 27, these women were different ages (20 to 24) in 1968, the first year of the survey and, therefore, of different birth cohorts. The *birth cohort* of a woman is an important correlate of fertility (Glick and Norton, 1977) and employment status (Farkas, 1977), and, therefore, we hypothesize, her economic well-being at age 27. Recent birth cohorts have been postponing both marriage and childbearing, which may lead to differences among women even over the small range of cohorts included in this analysis. Age in 1968 serves as a proxy for the birth cohort of a woman: the younger the woman in 1968, the more recent the birth cohort.

Because of the importance of parental socioeconomic level, race, and cohort,

these variables are included in each structural equation. A number of other exogenous variables were included in the analysis; they are discussed along with the appropriate endogenous variable. Going from right to left in Figure 1 we can now explicate the path model.

The *poverty status* of the woman's household at 27 is the only completely endogenous variable in the model. Whether or not a household is poor is by definition determined by its income and by the number of people dependent upon that income; therefore, no other exogenous variables were included in the structural equation. Household income is represented separately by the income of the woman and by the income of others in the household, while the number of children (not identical to household size, but correlated at the .90 level) represents the burden of dependency in these families. Since the husband earns most of the income in the vast majority of American households (Glick and Norton, 1977), this variable is expected to be the primary determinant of poverty.

The *woman's own income* is a function of the number of hours that she works and her hourly earnings.⁴ However, in the NLS, hourly wages were measured at the date of the survey, when only 38% of the women were employed (whereas 65% had worked some hours in the previous year and, therefore, reported some income during that period). Similarly, a substantial amount of information was missing on the respondent's current or last job. Therefore, neither predictor was included. Instead, we have a measure of work experience, and, of course, education; both of these represent the human capital a respondent may have accumulated. The income of other household members is also hypothesized to affect the woman's income. Those who have no other source of income will have a greater need to maximize their own earnings (see Hudis, 1976).

Other exogenous factors that may affect a woman's earnings reflect her own per-

⁴ Women who did not work any hours at all during the last year and women with no incomes over that period are included in the analysis.

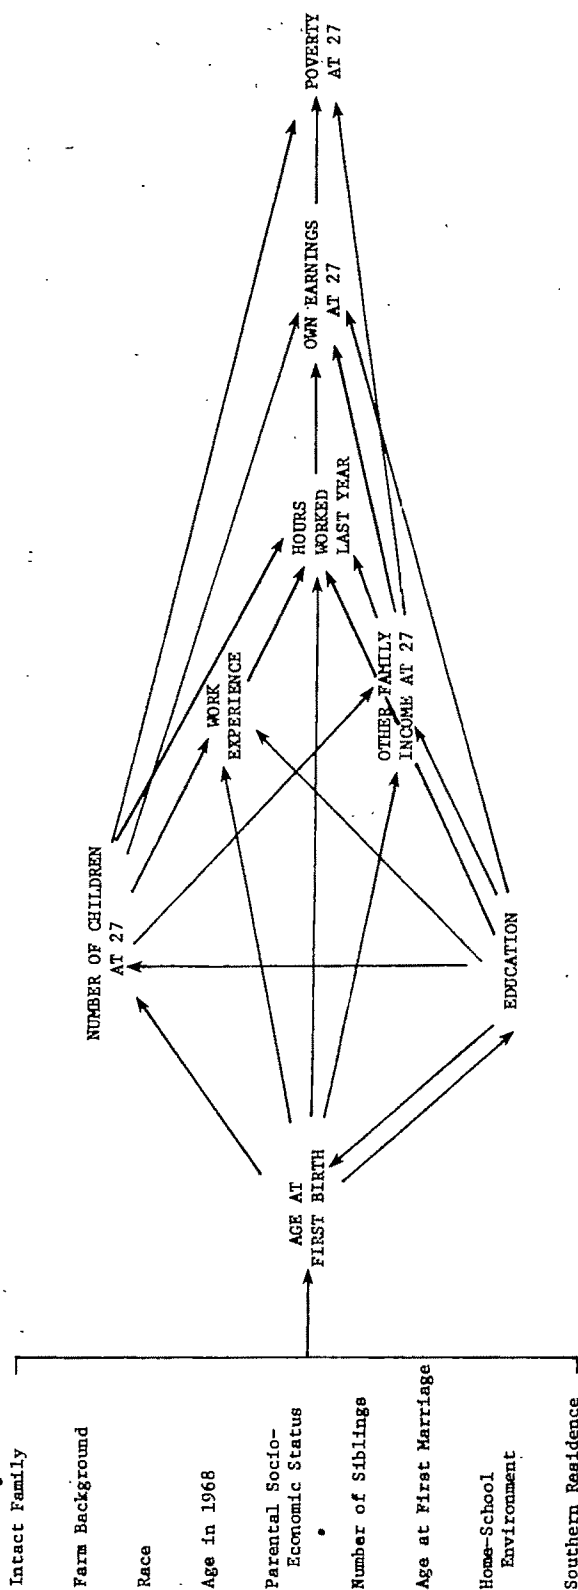

Figure 1: Schematic Diagram of the Effects of Age at First Birth on Socioeconomic Well-Being

sonal situation. Women who have young children (under six), who are enrolled in school, or who have a physical limitation of some sort, are likely, if employed, to earn less, trading off earnings for other factors such as convenience of hours, accessibility to work, and so on (see Darian, 1975; Hudis, 1976). We also have controlled for the residence of the respondent, in the South or in a metropolitan area, to reduce any differential in earnings due to differences in living costs. In addition to size of other family income we have controlled for the respondent's marital status. Although the two are strongly associated, their net effects may differ.

The primary component of *other family income* is the income of the husband, though other relatives may contribute, especially if the woman is not married. Determinants of the income of other adults in the household that are of interest in this analysis include a woman's age at first birth and her educational attainment and family size. Our expectation is that the early childbearers and women who themselves complete less education are likely to find their marriage prospects limited to men of lower earning ability. Other exogenous factors for which we have controlled in our analysis include southern residence and metropolitan residence, again, to limit cost of living differences. Finally, since larger households are likely to have more earners, we have controlled for the number of household members. Very little is known about the characteristics, such as education or occupation, of husbands or other household members; the residual for this variable is expected to be large as a result.

A woman's labor force participation (whether or not she works) has been found to be a function of her husband's income (see, for example, Bowen and Finnegan, 1969; Darian, 1975), her own education (Treiman and Terrell, 1975; Featherman and Hauser, 1976; McClendon, 1976), and the number and ages of her own children (Treiman and Terrell, 1975; Hudis, 1976; Sweet, 1968; Mason, 1974). Although the effects of each of these on hours may not be identical to their effects on participation,⁵ we have hypothesized that the

hours she worked last year are also a function of the income of others, her schooling, and her family size. Whether a woman works or not, and the hours she works, are probably also a function of her previously built-up human capital. Besides education, past work experience serves as a reasonable proxy for human capital. Researchers have found previous work experience to be among the best predictors of the current labor force participation of women (Heckman, 1978; Hofferth et al., 1978).

Age at first birth should affect *work experience*;⁶ however, the direction of the effect is not clear. Those women who postpone a birth may work in the meantime. On the other hand, early childbearers may be forced into the labor force sooner out of economic necessity. In earlier research we failed to find a strong direct effect of an early birth on work experience (see Hofferth et al., 1978); however, the women were of widely different ages and life cycle stages. Besides age at first birth, education and family size, as well as parental socioeconomic background, race, age in 1968, and age at marriage, background factors such as whether or not a girl was raised on a farm and whether or not her mother was employed when she was growing up may affect the work experience she accumulates (Cain, 1978). Finally, those who have never been married accumulate more work experience than those who have been married (Polachek, 1975).

Number of children has been found to be a function of education (Michael, 1974; Janowitz, 1976; U.S. Bureau of the Census, 1976a), age at first birth (Bumpass et al., 1978; Bonham and Placek, 1975; Presser, 1971; Furstenberg, 1976), number of siblings (Johnson and Stokes, 1976), and timing of the first birth with respect to marriage (Bumpass et al., 1978), as well as race, parental socioeconomic status, and birth cohort (U.S. Bureau of the Census, 1976b; Ryder and Westoff, 1971; Westoff

be working in any given year; however, they work fewer hours than do women not currently married (Hofferth et al., 1978).

⁶ The work experience measure used in this analysis is defined as the proportion of the last four years (before age 27) in which the respondent worked at least six months.

⁵ For example, married women are more likely to

et al., 1961; U.S. Department of Health, Education, and Welfare, 1976b). Although there is some evidence of a simultaneous relationship between labor force participation and fertility over the life cycle (see, for example, Waite and Stoltzenberg, 1976; Weller, 1977; Smith-Lovin and Tickamyer, 1978), we have assumed that, in our sample, number of children affects current hours worked, rather than vice versa, since all of these women have had a first birth prior to the year in which current participation is measured (age 27). The relationship of family size and prior work experience is more likely to be simultaneous; however, we do not have enough information to disentangle these effects.

A Nonrecursive Link between Education and Age at First Birth

Over half of the young women interviewed by the NLS research staff cited their marriage or pregnancy as the reason that they quit school. Since Mott and Shaw (1978) were able to return to the actual NLS interview schedules to develop codes for the month as well as the year of particular events, they were able to graph the parent status of young women relative to the month that they terminated schooling. Their data reveal that about 5% of the white high school drop-outs are already mothers when they leave school, as are about 20% of the blacks. By nine months after leaving school, nearly a quarter of the white high school drop-outs have become mothers, while 45% of the black high school drop-outs have. Looking at it from the perspective of the pregnant student, Mott and Shaw report that at the time of birth, fewer than 25% of blacks and 10% of whites are still enrolled in school. Clearly, pregnancy and childbirth affect school enrollment; however, it is also clear that there are other factors leading to school drop-out.

Cutright (1973) and others have suggested that it is a lack of motivation that causes both dropping out of school and early childbearing. According to this interpretation, we should find no relationship between pregnancy and school drop-out once motivation is controlled. An index consisting of measures of edu-

cational goals, parent-teacher help and encouragement to continue past high school, and the availability of reading matter in the home was developed as an indicator of motivation. We do not find, however, that the relationship between age at first birth and educational attainment disappears when this indicator of motivation is included in a regression. The relationship between early childbearing and schooling does not appear to be spurious. However, the relationship is very likely to be simultaneous. One might expect that a first birth to a teenager frequently precipitates the termination of schooling. It is also likely, though, that the longer a woman attends school, the longer she puts off marriage and childbearing. In this sense, educational attainment can be said to delay the first birth. This suggests that causality operates in both directions, though the particular direction that predominates depends on the sample.

Cross-tabulations of age at first birth with age at termination of schooling indicate that only among childbearers age 18 and under does either pregnancy or childbearing precede school drop-out in a substantial number of cases. Of those young women who have a first birth while 16 to 18, for example, 70% drop out of school within a year of birth (either one year before, in the same year, or in the following year). Of those who have a first birth between 19 and 21, only 25% finish schooling within one year of the birth. Most women who are 19 or older when they have their first birth have terminated their schooling before the birth. Given the importance of a high school diploma on the job market, the effect of terminating schooling on later life chances should be much greater if that termination occurs before high school graduation.

Thus, although we predict a simultaneous relationship between education and the age at which a woman bears her first child in the full sample, we expect the effect of age at first birth on education to predominate among those who bear their first at 18 and under. Among those who bear their first child at age 19 or older, we expect the effect of education on age at first birth to dominate. To test these expectations, we have specified simultaneous causality between age at first birth

and educational attainment at 27 not only for the total sample, but also for two subsamples: (1) women 18 or younger at the time of their first birth, and (2) women 19 or older at first birth.

Age at First Marriage and Age at First Birth

Marriage is a critical life cycle transition (Marini, 1978). An association between age at marriage and fertility has been documented repeatedly (Bumpass, 1969, for example). In addition, it has been shown that the age at which a woman first marries has a strong effect on the probability that she will later divorce or separate from her husband (Moore et al., 1978b). Yet in a society in which a substantial proportion of young married couples are contracepting, one can also argue that it is a birth, not a marriage, that drastically alters many aspects of a woman's life. This is especially likely to be the case for the earliest childbearers.

In general, women marry and then at some later point become pregnant and bear a child. That is, a marriage precedes childbearing in the majority of cases, and is the factor precipitating pregnancy. For example, in the NLS fewer than 7% of all women were found to have given birth premaritally. However, for many of the young women who bore first children while teenagers, the causal sequence may be reversed. For example, 17% of first births which occurred before a woman's nineteenth birthday were premarital, compared with only 4% of first births to women age 19 or older. Analyses of annual transitions to marriage indicated that if a birth occurred during a year to a young woman who was unmarried at the start of the year, the probability of marriage in that year was also dramatically increased (Moore et al., 1978b). Thus, a marriage, rather than being a cause of a birth, may be an outcome for the earliest childbearers. Of course, as suggested in the discussion of education and age at first birth, marriage as well as childbearing may be the result of some other, unknown factor, such as boredom with school. Unfortunately, in the NLS, data on marriage are not detailed enough to enable more pre-

cise comparisons of the timing of births, marriage, and school drop-out.

A model specifying simultaneous causation among schooling, age at first birth, and age at marriage is probably the best for the early childbearers (see, for example, Moore and Hofferth, forthcoming). Unfortunately, in this sample there are not enough exogenous variables associated with age at first birth and age at first marriage to statistically disentangle their relationship. However, leaving age at marriage out of the model in the analysis of young women whose first birth occurred before they were 19 significantly reduces its predictive power. Therefore, in the total sample and in the subsamples, age at first marriage was included as a control variable in the analysis of age at first birth.

Because we are interested in the effects of age at first birth, not age at first marriage, we also controlled for age at first marriage in each structural equation (except that of poverty). All effects of age at first birth are, therefore, net of age at first marriage. The high correlation between the two variables⁷ increases the error in the estimates of their separate effects; however, only among whites does their association rise above 0.70, the level at which bias appears most serious (see, for example, Hanushek and Jackson, 1977).

Age at First Birth and Later Economic Well-Being: Blacks and Whites

The literature on socioeconomic attainments of men and women demonstrates major differences in the attainment processes of blacks and whites (see, for example, Porter, 1974; Portes and Wilson, 1976; Hudis, 1977). Race cannot be justifiably included as an additive variable without dealing with the many race interactions. This is even more pertinent when considering the fertility related sources of differential attainments. For example, marriage is less likely to follow an out-of-wedlock conception of a young black woman than of a white woman. The

⁷ Age at marriage and age at first birth are correlated .654 in the total sample, .091 in the sample of early childbearers (≤ 18), .618 in the sample of older childbearers (> 18), .332 among blacks, and .770 among whites.

sources of other family income should also differ substantially for the two racial groups, with blacks more likely to receive support from public assistance and from household members who are not husbands (Hoffman, 1977). This should affect the relative importance of the two income sources and family size for poverty status. For these and other reasons we have estimated separately models of the relationship of age at first birth and later economic well-being for blacks and whites. Because of the small sample sizes we have not, in addition, divided the samples of black and white women by their age at first birth (≤ 18 , > 18).

RESULTS

As noted above, separate analyses were conducted on the total sample and several subsamples: (1) respondents who were 18 or younger when they had their first birth, (2) respondents who were 19 or older at first birth, (3) black women, and (4) white women.

There is evidence that the earliest childbearers do differ from later childbearers in a number of important ways. From the means (Tables 1 and 2) we see that parental families of early childbearers were lower on the socioeconomic scale, larger, and more likely to have been broken or to be black. Early childbearers were less likely than were later childbearers to have experienced an environment supportive and encouraging of furthering their schooling past high school. In addition, their first births were more likely to have been premarital. Thus it is not surprising that early childbearers have completed less schooling, have larger families, and are more likely to be poor at 27. Though there is little difference in their work experience, hours of work, or earnings, at 27 early childbearers are more likely to be living in the South, to be in large households, and to have physical problems limiting their activity. They are less likely to have a child under six. Net of the substantial initial differences between these two groups, does age at first birth continue to have an impact either directly or indirectly on later economic well-being? The results of the multivariate

analyses are presented in Tables 3 through 7.

Estimation of the Nonrecursive Link between Education and Age at First Birth

As depicted in the structural equations (Appendix), the number of (unique) exogenous variables left out of the age at first birth and education equations (two) is greater than the number of endogenous variables (two) minus one. Thus the model is over-identified, and two-stage least squares gives consistent unbiased parameter estimates. Because of the attention in economic and sociological literature recently to simultaneity problems (see, for example, Johnston, 1972; Duncan, 1975; Hanushek and Jackson, 1977), we will not discuss the problems of identification and estimation in simultaneous equations in detail.

The top two rows of Tables 3, 4 and 5 present the two-stage least squares (2SLS) estimates of the relationship between education and age at first birth for the total sample, for women whose first child was born when they were 18 or younger, and for those whose first child was born after they turned 19. Results of the models permitting simultaneous causality support the hypothesis that an early birth has a causal impact on schooling among the early childbearers (age at first birth ≤ 18 ; Table 4). Although the standardized coefficient is not large, the effect is substantial in actual years of schooling (metric coefficient). For each year she delays a first birth, a young woman can expect to complete 9/10 of a year of additional schooling. On the other hand, in this subsample there is no evidence that schooling affects age at first childbirth. In other words, the causal direction is from childbearing to schooling. The effect of the age at which a woman has her first birth is strong if she has that first birth while she is yet of high school age, but there is no evidence of reciprocal causation.

Among women who were at least 19 at the time their first child was born (see Table 5), the picture is quite different. In this subsample, the impact of a birth on educational attainment (about 1/5 of a year) is much smaller than it was for the

early childbearers, while the impact of schooling on age at first birth becomes significant and large (about 1/3 of a year). Indeed, among mothers at least 19 at their first births, the impact of schooling on age at first birth is about the same size (standardized coefficient) as the impact of a birth on schooling. Both effects are statistically significant; the relationship is reciprocal. This simultaneous effect is also found in the total sample, as would be expected from the predominance of older mothers in the sample as a whole (Table 3).

Thus the crucial causal impact of a birth on educational attainment seems to be concentrated among teenage mothers. This makes some intuitive sense. Among women who become mothers at older ages, more varied and personal factors are likely to affect schooling and the timing of childbearing. Among women who first become mothers during the high school years, however, the fact of that birth seems to intrude upon and supersede other factors that would normally determine educational attainment.

The Education-Age at First Birth Relationship among Blacks and Whites

Since such a sizeable number of black women bear their first children early and out-of-wedlock (U.S. Department of Health, Education, and Welfare, 1979), we would expect substantial differences in the age at first birth-education relationship between blacks and whites. In Tables 6 and 7 (metric coefficients), we can see that the effect of schooling on age at first birth is much stronger for blacks than for whites; whereas, the effect of a first birth on schooling is about the same for whites and blacks. As can be expected given the weaker relationship between birth and marriage among blacks ($r = .332$), the effect of age at first marriage on age at first birth is much weaker among blacks than among whites.

Direct, Indirect and Total Effects of Age at First Birth on Later Well-Being

Because we are only interested in the direct, indirect, and total effects of age at

first birth, not in the total association (due to common causes, correlated causes, and so on; see Alwin and Hauser, 1975), we have first eliminated the loop by semireducing age at first birth and educational attainment on their disturbances (see, for example, Heise, 1975), eliminated the paths due to exogenous variables, and redrawn the model to show only the variables endogenous to age at first birth and their corresponding paths (e.g., Figure 1).⁸ In Tables 3 through 7, the standardized and unstandardized coefficients for all relationships in the model, for each subsample, are presented.⁹ In Tables 8 and 9 we have summarized the path analyses by presenting in dollars the direct, indirect, and total effects of age at first birth on each endogenous variable.¹⁰ We focus here on the effects of age at first birth on the components of household income and on poverty, although the effects on the intervening variables also can be specified.¹¹ These results are calculated and presented separately for the subsamples of women divided by age at first birth and then separately for blacks and whites. Results are also presented for the entire sample in Table 8.

Direct Effects of Age at First Birth

As can be seen in Tables 8 and 9, there is only one statistically significant *direct* effect of an early birth. In the subsample of women who bore their first child at 18 or younger, age at first birth has a negative

⁸ Those variables exogenous to age at first birth drop out in the calculation of indirect effects.

⁹ Because the model does not fit Alwin and Hauser's (1975) paradigm, we have not used their "decomposition of effects" method. We have, instead, obtained the indirect effects by substituting in the structural equations, obtaining the reduced forms, calculating each indirect effect separately, and aggregating the indirect effects of age at first birth through each intervening and all later variables on own income, other family income, and poverty (see Appendix).

¹⁰ All relationships were estimated by ordinary least squares (OLS) except that between education and age at first birth, which was estimated by two-stage least squares (2SLS).

¹¹ In addition, to keep the discussion manageable we will not discuss the effects of the exogenous variables. The interested reader can glean a richer picture from a close examination of Tables 3-7 and Appendix Figures 1 and 2.

impact on other family income. Delaying a first birth by one year reduces other family income at age 27 by \$964 for each such year of delay, perhaps because the very youngest mothers get more help or delay household formation. With this exception, the effects of age at first birth on poverty are indirect, through its impacts on inter-

vening variables. The large negative effect of a first birth on the incomes of other family members will be discussed further when we discuss the total and indirect effects of a first birth among the early childbearers, as its ramifications upset preconceptions of a simple negative impact of early childbearing on later economic well-being.

The Total and Indirect Effects of Age at First Birth: Total Sample

Effect on own earnings. Postponing a first birth is definitely to a young woman's economic advantage. The total effect of waiting one more year before having a first birth is associated with increased earnings at age 27 of \$193 (Table 8). Thus a young woman who has a first birth at 22, compared with the one who has that birth at 17, can expect to earn almost \$1,000 more annually (in 1975 dollars) at age 27.

The largest of the indirect effects of age at first birth on a woman's earnings operates through *number of children*. Postponing a first birth is associated with reduced family size, which, in turn, is directly associated with increased earnings. It is indirectly associated with increased earnings through increased work experience and hours worked last year. Over half (54%) of the total effect is a result of the various indirect effects of a first birth through family size and later variables.

The next most important variables through which age at first birth exerts its indirect effects on earnings are *work experience* and *hours worked last year*; each accounts for about 20% of the total effect of a first birth on the respondent's earnings. However, the directions of these effects are opposite in sign. Postponing a first birth increases own earnings by \$65 for each year of delay because of the increased work experience and resulting increased hours and earnings such women will obtain. On the other hand, women who postpone a birth appear to have worked fewer hours last year (age 26-27), which reduces their earnings. Since whether or not a woman had a child under six was controlled, the direct effect of a first birth on hours worked last year can-

not be explained by the recency of a birth (recent mothers being more likely to be at home). In addition, the size of other family income is controlled; this effect is therefore not a result of the better economic position of the families of later childbearers. Other work on a different sample of women obtained a similar result (Hofferth and Moore, 1978); thus the finding can only be interpreted as evidence of the current lack of understanding of the factors associated with female labor force participation.

The smallest of the indirect effects of a first birth on a woman's earnings is that through *education* and later variables. It accounts for only 6% of the total effect. This is surprising, since much has been made of the importance of the effect of an early first birth in removing women from school. In fact, among women all ages at first birth, the effect of a first birth through education on later earnings is very small. However, this must be qualified since, as will be shown shortly, for certain groups of women the effects of an early first birth on later well-being through its effects on schooling are considerable.

Effect on other family income. As expected, the total effect on the income of other family members of delaying a first birth for one year is substantial. Each year of delay is associated at age 27 with other family incomes which are higher by \$477 (Table 8). Three-quarters of the effect is due to the *smaller families* such women will have, one-quarter is due to their greater *schooling*. Since we know so little about the husbands or other family members of these respondents, we are unable to explore those factors intervening between the family sizes or schooling of the women and the incomes of their husbands or other family members. However, it has been widely hypothesized that a more highly educated woman has both more opportunity to meet and is more attractive to highly educated men. Whether there is a common antecedent of large families and earnings of husbands or whether there is something about large families that reduces income (such as less geographic mobility), we are unable to sort out with these data.

Effect on poverty. As a result of the

woman's increased earnings and the larger earnings of other family members, as well as their smaller families, we expect that the probability of being poor at age 27 should be reduced among later childbearers. In Table 9, we can see that this is, in fact, the case. The total effect of delaying a first birth for one year decreases by 2.2 percentage points the chance that a young woman will be living at age 27 in a household that is poor. This is a substantial reduction (22%) in the probability of being in poverty, since the overall proportion in poverty in the total sample is only 10%.

Again, as in its effects on earnings and on other family income, most (80%) of the total effect is a result of the *smaller families* that postponers have; 12% is a result of their greater *schooling*, with 8% due to labor force participation. Of the latter, half the effect is positive and half negative. Although postponing a first birth increases a woman's *work experience* and her later earnings, decreasing her chances of being poor, it also decreases her *hours of work* at age 27, reducing her earnings and increasing her chances of being in poverty. These effects are almost equal, cancelling each other out.

Conclusions: total sample. Although age at first birth does not appear to have any direct effects on later earnings, income of other family members, or on poverty, it does have strong indirect effects. Most of these confirm popular beliefs about the negative effects of early childbearing on later economic well-being. However, there is also a positive effect of having a birth while young, which acts to increase work hours. The effect is small relative to the substantial negative effects of early childbearing on later well-being.

Another interesting and important result is that, contrary to many beliefs, the primary impact of having children early is that total family size is increased. The largest of the indirect effects of an early birth on later well-being operates through number of children. Women with larger families obtain less work experience, work fewer hours, and earn less. In addition, the incomes of their husbands or other family members are lower. As a result, they are considerably less well-off at age 27 than their later-bearing sisters. The

indirect impact of an early birth on a woman's own earnings through limiting her schooling is small, while that on the incomes of other family members through schooling, though somewhat larger, is still secondary to that through her own family size.

However, we have hypothesized that a first birth will have its strongest impact on educational attainment and thus indirectly on later well-being primarily among those still in high school at the time of the birth. Thus we have calculated the direct, total and indirect effects of a first birth on later well-being separately among earlier and later childbearers.

The Total and Indirect Effects of Age at First Birth: Age at First Birth Greater Than 18

For the majority of the sample, those who have their first births after age 18, the results are very similar to those for the total sample, as we would expect. The effects are in the same direction, and of the same order of magnitude (see Table 8). The strongest indirect effects operate through family size. The indirect effect of a first birth on own earnings through work experience is somewhat larger in this sample than in the total sample, and the effect through number of children is somewhat smaller. Because of the similarity of the effects and interpretation, we will not discuss this sample in detail.

The Total and Indirect Effects of Age at First Birth: Age at First Birth Less Than or Equal to 18

Effect on own earnings. The total effect of delaying a first birth on the earnings of the youngest childbearers is larger than that among childbearers of all ages. A woman's earnings are larger by \$276 for each year a first birth is delayed (Table 8). In contrast to the results among all childbearers, among the earliest childbearers the indirect effect of an early birth operates primarily through *education*. Because a woman who has a child early finishes fewer years of school, she has more children, obtains less work experience, and marries a man of lower earning power than a woman who delays

that birth one year. Larger family size and less work experience are associated with lower earnings, with lower family incomes, and with poverty. Seventy percent of the total effect of a birth on own earnings operates through education and later variables. Another 30% operates through *number of children*. The very youngest mothers have larger families. As a result they accumulate less work experience, which is associated with working fewer hours, and earning less.

Effect on other family income. A surprisingly large direct negative effect of postponing a first birth on other family income at age 27 was obtained in this sample. Though there are substantial positive effects of delaying a first birth on other family income through increased *education* and through decreased *number of children*, the direct negative effect of a first birth is so large as to make the direction of the total effect negative. As a result, a one-year delay in a first birth is, among the early childbearers, associated with a \$539 reduction in the incomes of other family members (Table 8). Although surprising, analyses on another sample (the Panel Study of Income Dynamics) showed the same negative impact in a comparable subsample of early childbearers (Hofferth and Moore, 1978). Because of lack of information on other family members, we have no way to compare the family situations of early and later childbearers in detail. Other analyses that have been conducted with both the NLS and the PSID, however, shed some light on this relationship. They suggest that the older (of the early) childbearers are more likely than the younger to marry as a result of a pregnancy or a birth (Moore et al., 1978b). Thus, it may be that early childbearers who do not leave their parental home, with its support and help, to start their own families, may therefore be able to avoid many of the negative consequences of early childbearing (see, for example, Furstenberg and Crawford, 1978). The early marriers with children may be hardest hit by the problems of role transition so often cited by writers on this subject. Evidence that it is early marriage rather than an early birth that is associated with later marital dissolution supports

this argument (Moore et al., 1978b). Thus, more important than the fact of an early birth may be whether or not the young woman can draw upon enough social, economic, and emotional support to be able to continue with her life, including finishing school and not immediately risking further pregnancies.

Effect on poverty. As a result of the large direct effect of a birth on other family income, the total effect of delaying a first birth on the chance of being in poverty at age 27 is small (Table 8). Half the indirect effects of delaying a first birth on the probability of poverty are negative—through increased *education* and decreased *family size*, which increase later earnings and decrease the chance of being in poverty at age 27. However, a large indirect effect through other family income acts to increase the probability such a woman will be poor at age 27. The positive and negative effects are comparable in size, thus cancelling each other out.

Conclusions: sample of early childbearers. Although we did find that, among all childbearers, delaying a first birth has substantial positive indirect effects on later well-being through education, family size, and labor force participation, the effects of age at first birth on later economic well-being through educational attainment are not nearly as large or as significant as are the effects through family size. As predicted, only among the earliest childbearers, those who have a first birth before or at 18, are there large indirect positive effects of delaying a first birth on later earnings through education. However, among these young mothers, the very earliest childbearers (those who have a first birth at 15 or younger) may be better off, or not affected at all by the birth, because the incomes of other family members are larger. We speculate that the reason for this result may be that the very youngest are least likely to leave the parental home.

The Total and Indirect Effects of Age at First Birth: Blacks and Whites

This complicated process is explored further by dividing the sample by race.

Black and white women tend to differ significantly in their responses to early childbearing. Most notably, black teenagers are much less likely to marry as a result of pregnancy. Although the correlation between age at first birth and age at first marriage is .77 for whites, it is only .33 for blacks. Only 3% of first births to whites are premarital, compared with 34% of first births to blacks. Comparing average ages at first marriage and first birth of black and white women (Table 2), we see that whereas the mean age at marriage is about two years younger than mean age at first birth for whites, for black women age at marriage is higher than age at birth by exactly one year. Even among white women who have a first birth at or before reaching age 18, the average age at first marriage is lower (about a quarter of a year) than mean age at first birth. This reflects the much higher likelihood that a young white woman who has a first birth will marry at or before the birth than will a black woman. Yet even net of their different probabilities of marriage, the impact of an early first birth differs among black and white women.

In Table 9 the effects of being one year older at first birth on measures of economic well-being at age 27 are shown separately for blacks and whites. As we would expect, the results for white women and for the total sample (see Table 8) are very similar, since whites predominate numerically. Among whites, delaying a first birth substantially increases own earnings and other family income while it reduces the probability of living in poverty at age 27.

However, among black women the results are quite different. The surprising result is a small but negative total impact of being older at first birth on the earnings of a woman at age 27. It is primarily due to the weak links between schooling and later work experience and between schooling and the earnings of black women. These coefficients are positive, but not statistically significant. Schooling affects work experience only indirectly, through its effects on family size. Thus the indirect effects of age at first birth on own earnings through schooling are smaller among black than among white women.

The indirect effect of a first birth through family size is positive but smaller for blacks than for whites. In addition, through work experience there is a negative indirect impact of being older at first birth on the earnings of a woman at age 27 which offsets some of the positive effects of delayed childbearing. In contrast to whites, among blacks older childbearers accumulate *less* work experience, which reduces their hours worked and earnings. As a result of this negative indirect effect and the weak positive indirect effects described above, the total effect of a first birth on later earnings is slightly negative in this sample of blacks.

The finding that delay of a first birth is associated with less work experience among black women is surprising. The absence of a link between schooling and labor force experience and earnings also is unexpected. Taken together these results suggest that black teenage mothers move relatively quickly into the labor force, perhaps out of necessity, but perhaps out of an awareness that additional schooling would not translate into economic advantage anyway. In addition, among blacks, late childbearing is less frequent. Of the women having a birth by age 27, only 14% of the black women delayed past age 21, compared with 36% of the white women. As a result, black late childbearers may differ in important ways from their early childbearing sisters, ways we are not able to measure with these data. Finally, the sample size is very small, which may partially account for the lack of effects; however, other analyses have also failed to find strong effects of age at first birth among black women (see Moore et al., 1978a).

Conclusions: blacks and whites. Age at first birth does not appear to be as great a handicap for the black woman as it is for the white woman. Since teenage sexual activity and pregnancy are much more common among blacks than among whites (Zelnik and Kantner, 1977; 1978), social mechanisms for dealing with it and the children that result appear to be better established in black families and neighborhoods (see Stack, 1974, for example). Alternatively, since so many other factors handicap the black woman, the impact of

an early first birth may not be clearly distinguishable from the rest. Among both black and white women the primary *negative* indirect impact of an early first birth on later economic well-being is through its impact on family size. An early first birth means more children by age 27, with its concomitant negative impact on labor force participation and earnings. However, among black women, early childbearers accumulate more work experience than later childbearers, increasing their earnings at age 27. Thus an early first birth is associated with somewhat higher well-being among blacks; among whites, early childbearing predicts substantially lower income.

An early first birth has no impact directly or indirectly on the incomes of other family members and very little on the probability of being poor among blacks, whereas there is a substantial negative impact of an early first birth among whites both on other family incomes and on the probability of being poor at age 27.

DISCUSSION AND CONCLUSIONS

The age at which a woman bears her first child has important effects on her later economic well-being. With one exception, the effects of an early birth are indirect; they operate on later economic well-being through their impacts on family size, schooling, and labor force participation.¹² In general these indirect effects are negative; delaying a first birth does increase the well-being of a woman at age 27. However, even to say this much oversimplifies the complicated chain of associations between early childbearing and later economic well-being. The negative effects were expected: early childbearers have larger families, complete less schooling, and obtain less work experience; consequently, they earn less themselves, other family members earn less and they are more likely to be living in

poverty. However, there are several positive effects of early childbearing on income. Because early childbearers appear to work more hours at age 27, they are slightly better off. And, in addition, among the early childbearers (18 and under), the very earliest (age 15 or 16) may be better off than their sisters who have first births at age 17 or 18, due to the larger incomes of other family members among the former. This surprising result cannot be explained adequately with these data. However, drawing from other related work, we have suggested that it may be the greater likelihood that 17- and 18-year-old girls will leave the parental household that decreases their economic well-being later on. Those who marry leave the support of their parents to enter into unstable unions. Certainly their chances of having more children are increased, and they may be unable to obtain the human capital (either through schooling or through work) that would enable them to support themselves and their children when the necessity arises.

Overall, of course, later childbearers are much better off than early childbearers. The most important indirect effect of delaying a first birth is that total family size at age 27 is reduced. As a result, the total work experience, hours worked, and earnings of women, as well as the incomes of their husbands or other family members are higher. Net of family size, delaying a first birth increases the work experience a young woman obtains, which raises her hours worked and her earnings. This suggests that women who work either before marriage or between marriage and the arrival of a first child do build up substantial human capital, compared with those who have a first birth before entering the labor force.

Among the total sample, the indirect effect of an early first birth through schooling is small. An early first birth does lower the total amount of education received, and, therefore, the incomes of the woman and of other family members; however, the effect is important and large only among those who have that first birth while still in high school. Other research indicates that the effect of a first birth in removing women from the educational

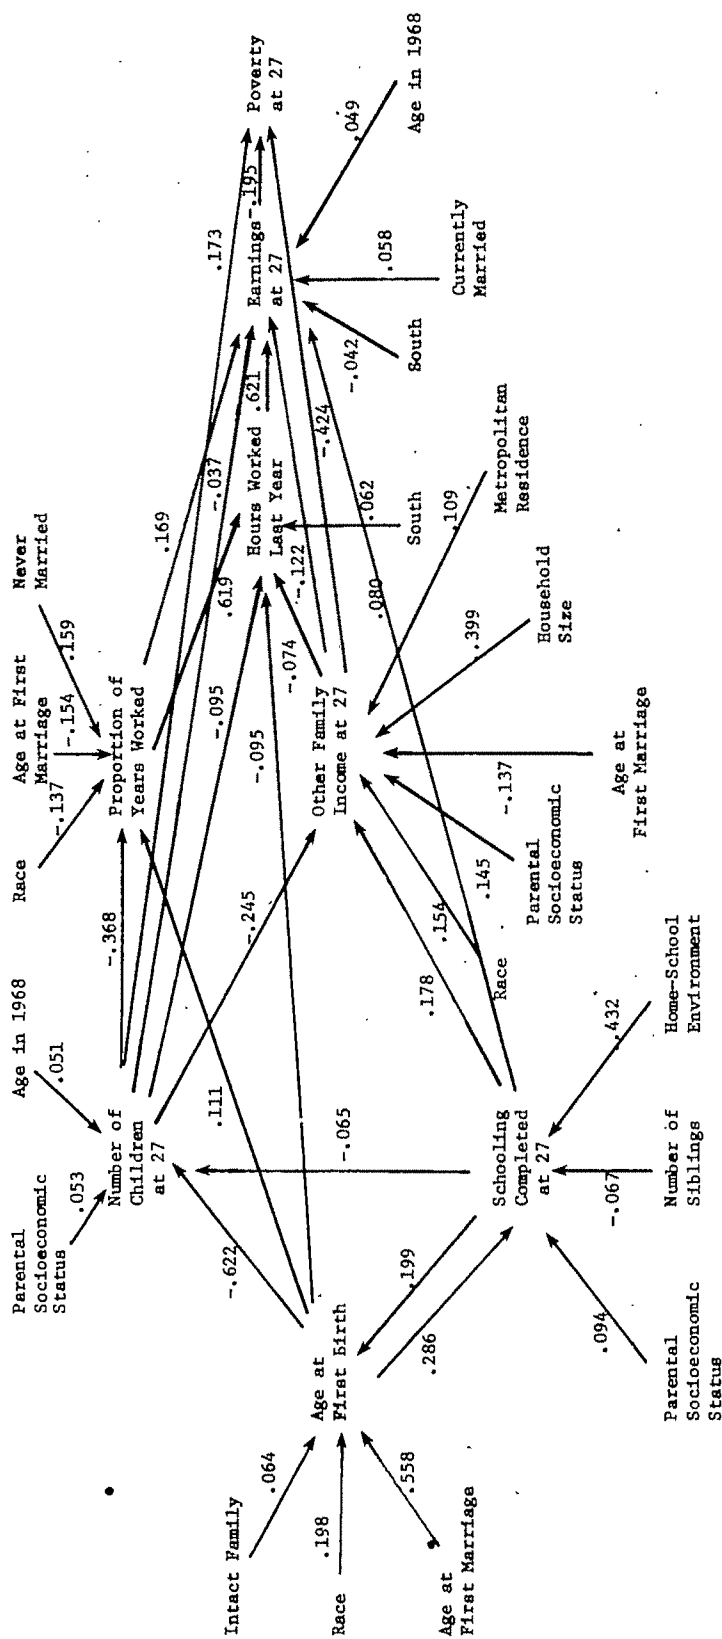

¹² The one direct effect (on other family income) would disappear if we were able to specify the appropriate intervening variables. In this data set, however, there is not enough information on other family members to do so.

system declines with years of schooling completed, with its strongest effect occurring during high school and between high school and college (Moore et al., 1978a).

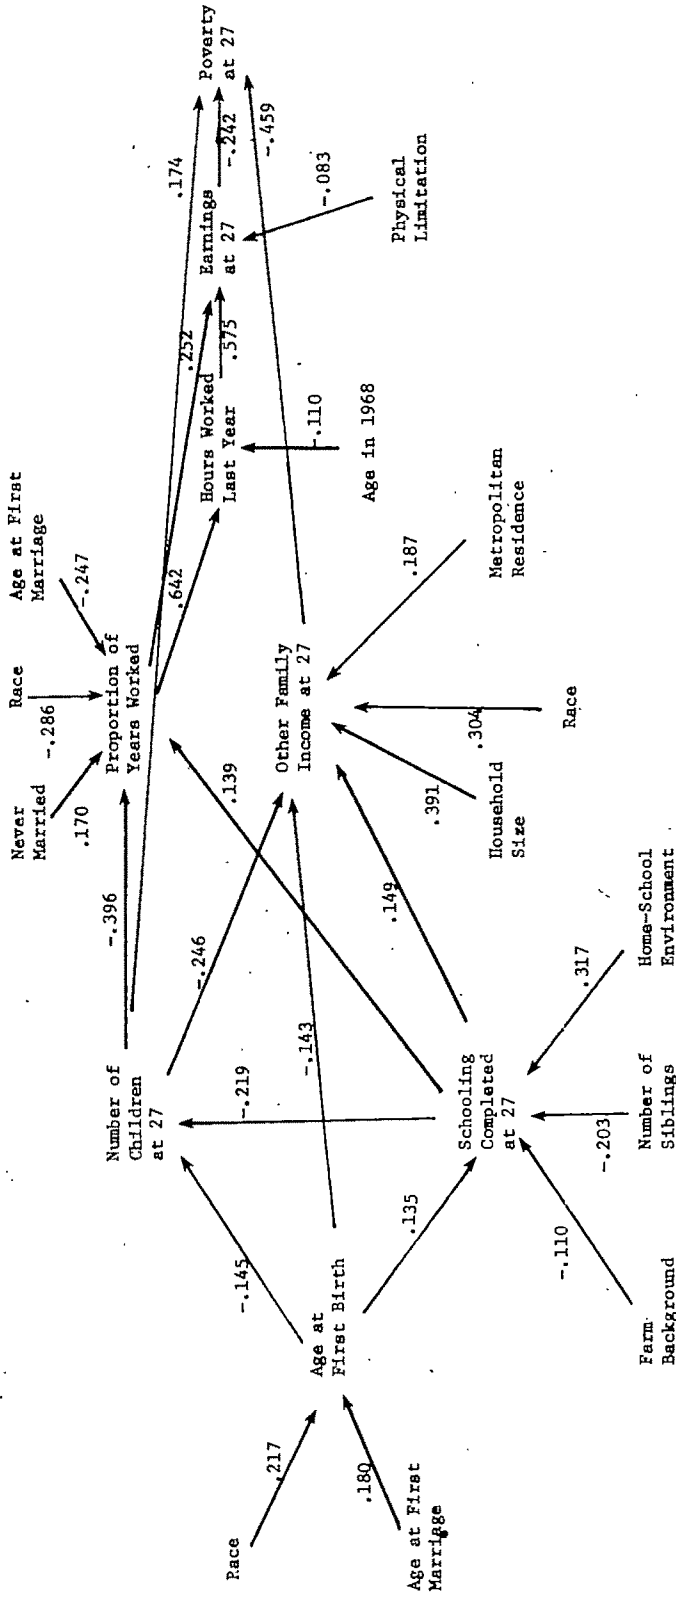

Of course, these women are still relatively young. Most have not completed their childbearing; some may return to school; most will work. Therefore, the size of the effects of age at first birth among these women at the end of the childbearing period is unknown. It appears most probable that using a fixed age-point midstream understates the effects of age at first birth. Of the balance of forces, the positive effects of later childbearing are likely to continue into the future (through greater schooling and smaller family size), more than the negative effects through hours worked last year. This is particularly so since the main component of this negative link is likely to be the age of the youngest child, a variable that changes much more regularly towards higher employment than does the number of children in the household (as a consequence of family size). In addition, the very late childbearer is excluded from the sample. Since such women are likely to be much better off economically, their exclusion also suggests that we have underestimated the effects of an early first birth.

What are the implications of this research for researchers and policy makers? The implication for analysts of status attainment lies in the importance of including age at first birth, and perhaps age at first marriage, in models of the attainment of women, and presumably, for men as well. This type of analysis raises more questions about the relationships among the labor force participation of women, marriage, fertility, and socioeconomic well-being than it answers; however, new questions often lead to new discoveries.

For policy makers the primary implication of this research is that teenage childbearing appears to have fairly long-lasting negative consequences. Preventing teenage pregnancy is, of course, the most effective way to break the link between early childbearing and poverty. However, by tracing the causal associations we have established other points of intervention: between an early birth and lowered schooling, between an early birth and larger total family size, and between an early birth and lowered work experience, as well as between points later in the causal chain. In addition, the sizes of the indirect effects in the different subsamples suggest the relative effectiveness of various types of program interventions following a first birth in reducing the chance a mother will end up in poverty. The primary indirect negative impact on household income of an early birth to a teenager operates through schooling. This suggests as an important program focus special school programs, combined with infant day care, so that the high school student might finish. The surprisingly small impact of an early birth on later well-being among the very earliest childbearers suggests that policies enabling unmarried mothers to remain with their families or other relatives rather than encouraging them to form their own households may be desirable. Once they are out of high school, the indirect negative effects of an early birth operate primarily through increased family size and lowered work experience. Such young women need access to family planning services to delay subsequent births, thus reducing total family size. Also following logically from our research are policies such as job counseling and training to break the causal association between early births and later economic well-being.

ENTRANCE INTO THE ACADEMIC CAREER*

J. SCOTT LONG

Washington State University

PAUL D. ALLISON

ROBERT MCGINNIS

Cornell University

American Sociological Review 1979, Vol. 44 (October):816-830

This paper examines the initial academic placement of 239 male, Ph.D. biochemists. Position in the academic stratification system, according to the normative structure of science proposed by Merton, should be allocated universalistically on the basis of a scientist's contribution to the body of scientific knowledge. Our analyses, however, show that after controlling for the effects of doctoral origins and the prestige of the mentor, preemployment productivity has an insignificant effect on the prestige of the scientist's first academic position. This basic finding is elaborated by examining the effects of postdoctoral fellowships, additional characteristics of the doctoral department, and the academic rank of the position obtained. In no instance does preemployment productivity affect the prestige of the first job. The universalistic nature of the scientific stratification system is assessed by comparing those factors which determine job allocation to those which predict scientific productivity later in the career. It is found that prestige of a scientist's first teaching position is least influenced by those factors which are most predictive of future productivity and most influenced by those factors which are likely to involve ascriptive processes.

One of the most persistent findings in the study of stratification in science is the substantial correlation between the prestige of the university department which currently employs a scientist and the prestige of his doctoral department (Caplow and McGee, 1958:225; Berelson, 1960:127; Crane, 1965; Hargens and Hagstrom, 1967; Hagstrom and Hargens, 1968; Cole and Cole, 1973:98). This relationship suggests two alternative interpretations. First, the correlation may be evidence for the operation of ascriptive or particularistic hiring patterns. This would be true to the extent that the prestige of a student's doctoral department aids him in obtaining a prestigious academic appointment, independently of his demonstrated ability. Second, the prestige of a student's doctoral department may be associated with factors indicating his ability as a scientist, and hence the correlation between doctoral prestige and the prestige of the hiring department

would reflect the universalistic allocation of rewards in the scientific community.

Evidence for these alternative explanations is mixed. When both doctoral prestige and measures of scientific productivity are introduced into analyses predicting current prestige, the effect of doctoral prestige is somewhat reduced (Hargens and Hagstrom, 1967; Cole and Cole, 1973:98). Nevertheless, the effect of doctoral prestige remains significant and approximately equal to (or greater than) the effect of productivity. This result suggests *at least* a partial departure from the norm of universalism in science which requires that "scientific careers be open to talent" and that "recognition and esteem accrue to those who have best fulfilled their roles, to those who have made original contributions to the body of scientific knowledge" (Merton, 1973:272, 293). Indeed, on the basis of her findings, Crane (1970:961) concluded: "It could be argued that despite the system's normative commitment to universalistic criteria, they are not utilized in practice." In short, past studies do not support the contention that academic position is allocated exclusively, or even largely, on the basis of scientific productivity.

This lack of correspondence between scientific productivity and academic position is not simply a temporary inequity

soon to be corrected by later mobility, but has lasting consequences for the individual scientist. Hagstrom and Hargens (1968) report a correlation of .68 between the prestige of first and current positions (which may be the same) for scientists in four fields. Even when they exclude those scientists who received their degrees less than 25 years earlier, the correlation was over .65. Moreover, for every subgroup studied the prestige of the first job was a much better predictor of the prestige of the current job than was the current number of publications. It should be noted, however, that these high correlations are partly a consequence of the fact that many scientists remain in the same department for most of their careers. For those who do change jobs, the correlations are much lower (Allison, 1976:207; Long, 1978). Nonetheless, given the immobility of many scientists, where a scientist ends up depends largely on where he starts, as Caplow and McGee (1958:225) have suggested.

The initial misallocation of position may be not only unfair to individual scientists, but also potentially damaging to scientific progress. As Zuckerman (1970:246) has suggested, regardless of the mechanism by which the first academic job is allocated, being located at a university with superior resources and stimulating colleagues should give the young scientist a significant boost in his career. Many of the rewards associated with prestigious departments are also prerequisites for future productivity (cf. Cartter, 1966; Brown, 1967; Clark et al., 1976). And indeed, Long (1978) has shown that departmental location has a major impact on a scientist's future productivity. Consequently, to the extent that prestigious position and valuable resources are allocated to those not best able to utilize them, overall scientific productivity may be reduced.

It now appears that earlier studies have *overestimated* the effects of productivity on the prestige of current affiliation. Hence, the violation of the norm of universalism may be more serious than previously thought. The problem arises from the fact that these studies (with the exception of Crane, 1965) measured departmental prestige and individual pro-

ductivity at the same point in time, raising the possibility that it is the prestige of the department (or its correlates) that affects productivity rather than the reverse. With longitudinal data, Long (1978) has presented evidence for just this possibility. In this paper we extend those results by showing that the prestige of a scientist's first teaching position is least influenced by those factors which are most predictive of future research productivity and most influenced by those factors which are likely to involve ascriptive processes.

Before turning to the data, let us briefly consider how the first job might be allocated. It is worth remembering that academic jobs are not allocated by some master decision maker, but by a market mechanism in which departments compete for the most desirable candidates. The process occurs in three stages: candidates decide which jobs to apply for, departments choose candidates for the vacancies, and candidates choose among the offers they receive. Since the candidates themselves play such a large role in the final outcome, it would be misleading to interpret observed correlations between departmental and doctoral prestige as indicative only of *departments'* preferences and procedures (Cole and Cole, 1973:97). Nevertheless, most new Ph.D.s stress the importance of prestige or its correlates in choosing jobs (Brown, 1967), and we will not take this as problematic.

Assuming, then, that prestigious departments have a competitive advantage in recruiting new faculty, the question becomes which characteristics of students provide them with a competitive advantage over others? Suppose that departments recruited new Ph.D.s in a completely universalistic fashion. If universalism means choosing those candidates who have made the greatest scientific research contributions, then we would expect the number and estimated quality of predoctoral research publications to be major criteria. But new doctorates have not had much time to demonstrate their ability through publications. The evaluation of those publications is further complicated by the fact that many of the predoctoral publications are coauthored with

the dissertation supervisor or other faculty members who may have played the major role in the design and interpretation of the research.

It is much more reasonable to expect universalistic departments to base their decision on expected *future* scientific contributions, and these expectations legitimately may depend on many factors besides predoctoral productivity. It may be that the prestige of the doctoral department is in fact a good indicator of future productivity, either because prestigious departments manage to recruit the best students or because they provide superior training. In fact, Cartter (1966) showed that subjective ratings of departments' effectiveness of graduate training were correlated almost perfectly with a measure of departmental prestige. For exactly the same reasons, the reputation of a new doctorate's dissertation supervisor—hereafter referred to as the mentor—may be a reasonable indicator of a scientist's future performance.

While there are only a few optimal ways to practice universalism, particularism can have many faces. Caplow and McGee (1958:127–8), for example, have suggested that departments choose candidates almost entirely on their expected contributions to the prestige of the department: "Men are hired, to put it baldly, on the basis of how good they will look to others." As a consequence, departments give only a cursory examination of the candidate's written work and concentrate, instead, on where he comes from and who recommends him. Such a process may still appear to be universalistic if disciplinary prestige is associated strongly with research productivity. Moreover, if departments really want to hire the most prestigious candidate, they will conduct a wide search and not give preference to other criteria.

More insidious is the notion that academic jobs are secured primarily through social ties. Many studies have shown that blue-collar workers find most jobs through friends and relatives (see references in Granovetter, 1974:4–5) and Granovetter (1974) finds a similar pattern for professional workers, at least according to self-reports. Caplow and McGee (1958:110)

argue that departments often choose candidates on the basis of their social ties to the department. Inbreeding, the hiring of a new Ph.D. by his own doctoral department, is surely the most direct linkage. Somewhat more typical may be two-step ties in which the candidate is recommended by a friend of someone in the hiring department or a graduate of that department. To the degree that such ties are stratified, such a process should produce correlations between the prestige of the candidate's origin and the prestige of his destination.

All of these factors—past scientific contributions, expected future contributions, disciplinary prestige, and social ties—probably have some influence on the allocation of academic positions. Since each is consistent with a positive correlation between doctoral prestige and prestige of current position, it is difficult to assign relative weights to each factor. Nevertheless, the results presented in the remainder of this paper favor a particularistic interpretation. Specifically, it is shown that preemployment productivity has little if any impact on the prestige of the first position even though it is the best predictor of future productivity. While doctoral prestige has the strongest impact on the prestige of the first position, it has a much smaller impact on future productivity. Finally, it does not appear that departments make much use of any departmental-specific predictors of future productivity other than those that we have measured.

DATA AND MEASUREMENT

The sample consists of 239 male biochemists who received their Ph.D.s in fiscal years 1957, 1958, 1962 and 1963 and whose first faculty position was in a graduate department rated by Roose and Andersen (1970).¹ Career histories were

¹ Analysis was restricted to male biochemists due to the small number of females who obtained doctorates in biochemistry during this period, and to the difficulty in obtaining complete information on those females who did obtain degrees. Work is currently in progress to collect complete information on these females. Complete scores from the Roose and Andersen study were kindly provided by Charles J. Andersen.

obtained from *American Men and Women of Science* (tenth, eleventh and twelfth editions). The prestige of the doctoral department was measured by the complete three-digit rating of faculty quality of biochemistry departments, a partial listing of which appeared in Cartter (1966). These scores ranged from 100 for the least prestigious to 500 for the most prestigious. The prestige of the first job was somewhat more difficult to measure since the biochemists worked in several departments. Accordingly, a prestige score for each university was constructed based on a weighted average of the Roose and Andersen (1970) ratings of the departments of biochemistry (1/2), chemistry (1/4), physiology (1/12), microbiology/bacteriology (1/12) and pharmacology (1/12).² These scores also ranged from 100 to 500.

For all but two of the sample, the name of the mentor was obtained from *Dissertation Abstracts*, *Directory of Graduate Research*, or a mail survey of graduate deans. A measure of the mentor's accomplishments was obtained by counting citations to his or her first-authored publications in the 1961 *Science Citation Index*. While we will interpret these counts as a measure of prestige, it should be kept in mind that they may reflect both the performance of a scientist and his or her standing in the scientific community.

Productivity of the sample members was measured using counts of both publications and citations to them. *Chemical Abstracts* (1955-1973) was used to locate the articles published by the sample members, whether or not they were the senior author. Citations to these articles were coded from *Science Citation Index* (Vols. 1961, 1964, 1966, 1968, 1970, 1972, and 1974). The name of the first author on multiple-authored papers where the cohort member was not the first author was used to locate citations to junior authored papers; thus downward bias in counts for scientists who were predominantly junior authors was avoided. For a given year in the scientist's career, the publication measure reflects publications

in a three-year period ending in that year. The citation measure for that year is restricted to citations to papers published in that three-year period. Since coverage of *Science Citation Index* and *Chemical Abstracts* increased during the period covered by our analyses, counts were standardized within years of the Ph.D. For details, see Long (1978).

In addition to these key variables, Astin's (1971) measure of "selectivity" of the scientist's undergraduate institution was used. This index has values ranging from one to seven, with seven being the most selective category. This measure has been interpreted by some as a crude indicator of intelligence and by others as a measure of the quality of the undergraduate education. In any case, a number of studies have shown it to be a moderately good predictor of future success.

RESULTS

Consistent with earlier studies, we find a correlation of .39 between doctoral prestige and prestige of the first job. Destination prestige also has a correlation of .34 with mentor's citations, .22 with both undergraduate selectivity and citations, and .14 with publications. Equation 1 of Table 1 presents the results of entering these variables into a single regression equation. Doctoral prestige clearly has the strongest effect, followed by a moderate but significant effect of the mentor's prestige and a slightly weaker effect of baccalaureate selectivity. On the other hand, the effects of the two productivity measures are small, inconsistent in sign, and statistically insignificant. These results are similar to those reported by Long (1978) for a special subset of this sample.

For a clear interpretation of these findings, it is instructive to note the different effects of doctoral prestige and mentor's citations on the preemployment productivity of students, and their similar effects on the prestige of the initial academic position. While the prestige of the mentor and the doctoral department are moderately correlated ($r = .41$), they have quite different effects on predoctoral productivity. When the number of predoctoral publications and citations of our sample

² These weights (contained in parentheses) were based on estimates of the number of biochemists teaching in each field.

Note: Dependent variable is the Roose-Andersen bioscience prestige score of the first academic position. Item identifications are: PHD=Ph.D. prestige, Cartter prestige of the Ph.D. department; MENT=square root of five-year citation counts for mentor; SEL=selectivity of baccalaureate institution; PUB=publication level, square root of standardized levels of three-year publication counts ending in the first year of the first job; CIT=citation level, square roots of standardized values of citations to publications in the three-year period ending in the first year of the first job; ENRL=number of biochemistry graduate students enrolled in the doctoral department in 1962.

* Row β gives standardized regression coefficients; row b gives unstandardized regression coefficients; row t gives the t-statistics (with more than 120 degrees of freedom in the regression, critical values for a two-tailed test of significance at the .10, .05 and .01 levels are: 1.645, 1.960 and 2.576, respectively; for a one-tailed test the critical values are 1.282, 1.645 and 2.326 for significance levels .10, .05 and .01, respectively); row r gives zero-order correlation coefficients with dependent variable.

members are regressed on doctoral prestige, mentor's citations, enrolled time in graduate education and baccalaureate selectivity (regressions not shown), the effects of the mentor's prestige are strong, positive and statistically significant, while those of doctoral prestige are trivial and statistically insignificant. These results hold even after controlling for the extent of predoctoral collaboration with the mentor (regressions not shown). Yet, the influence of the mentor on his or her student's first academic position is weaker than that of departmental prestige, and operates directly rather than indirectly through the effect of productivity on departmental prestige of the initial academic appointment.

Our initial conclusion, then, is that neither the quantity nor the "quality" of one's early publications has significant influence on where one ends up in the prestige hierarchy. In the remainder of this paper, the baseline model presented in Equation 1 of Table 1 will be elaborated

in several ways. *In no case are any effects of productivity on the prestige of the first job found.*

Preemployment productivity. This lack of effect cannot be explained by any lack of variation in preemployment productivity. The publication measure used in Equation 1 had a mean of 2.8, a median of 2.2 and a variance of 5.7. The range was from 0 (14.6% of the cases) to 13 (0.4% of the cases). There was even more variation in the citation measure: the mean was 13.6, the median was 6.7, the variance was 260.4, and the range was from 0 to 90.

Neither are the results attributable to an improperly specified functional form. Although only results using a square root transformation of the productivity measures (used to reduce skewness) are reported, logarithmic and cube root transformations, as well as the untransformed counts, were tried. To eliminate further the possibility of bias or attenuation due to improper functional form, the productivity measures were entered as sets of

dummy variables. In addition to raw citation counts, the mean number of citations per paper was also tried as perhaps a better indicator of a candidate's ability. Finally, articles and citations to them which were not the result of coauthoring with the mentor also were examined. None of these measures had a significant effect on destination prestige. Thus it appears to be highly unlikely that the lack of effect of productivity is due to the way in which productivity was measured.

Doctoral prestige. It is possible that the effect of doctoral prestige is a consequence of its correlation with some other, more fundamental variable. Several characteristics of the doctoral institution were examined including Astin's (1971) measure of selectivity, whether or not the department was administratively located in an agricultural school, the percentage of all students who were graduate students, the year the first Ph.D. was awarded, the dollar amount of funding in 1964 from the National Institutes of Health (the principal agency supporting biochemical research), and several indicators of the size of the institution and its components. Only the number of biochemistry graduate students enrolled in 1962 had a significant effect on the prestige of the first job. Its effect was sizable and negative as shown in Equation 2 of Table 1. The coefficients for both mentor's citations and undergraduate selectivity were reduced by this addition to the model, but the effect of doctoral prestige increased by 50%. This increase is the result of the .60 correlation between enrollment size and doctoral prestige, and the fact that these two variables have effects on destination prestige that are opposite in sign.

Three explanations for the negative effect of enrollment seem reasonable. First, large enrollments may reflect more lenient admissions policies and thus lower average ability of graduates. Second, large enrollments may reduce the effectiveness of training during the graduate education. And finally, large enrollments tend to produce large graduating cohorts and the increased competition for available jobs may hurt all of the graduates of a department. Although we cannot distinguish empirically among these three explana-

tions, biochemistry enrollments will be added to the baseline model for the remainder of the analysis.

In Equation 3 of Table 1 we examined the possibility that there are other, unmeasured characteristics of institutions or departments which might help or hinder their doctorate graduates. This was accomplished by adding a set of 20 dummy variables representing the 20 biochemistry departments which graduated three or more of the doctorates in our sample. While these 20 departments represented only 29% of the producing departments, they accounted for 64% of the biochemists in the sample. The addition of these dummy variables increased the R^2 from .24 to .35 ($F_{20,210}=1.79$, $p<.01$), indicating that there are significant differences among departments in the prestige attainments of their graduates that cannot be attributed to the prestige of the doctoral departments themselves. For example, Johns Hopkins has a coefficient of -32, while Chicago has a coefficient of 65. This says that once the effect of origin prestige, mentor's citations, undergraduate selectivity and the individual's productivity have been removed, Hopkins graduates averaged 32 points lower and Chicago graduates 65 points higher in destination prestige than graduates of the 49 departments not represented by dummy variables. Moreover, net of other variables, the difference between the attainments of Hopkins graduates and Chicago graduates, 97 points on the prestige scale, is more than one standard deviation. Differences of this sort are very likely substantial, yet do not lend themselves to a simple explanation. None of the characteristics of departments and institutions that were mentioned above account for these differences, and from Equation 3 it is clear that they persist after controlling for departmental prestige, productivity of the mentor and individual productivity. It may be that they reflect peculiar characteristics of individual departments at a particular point in the history of the discipline or errors in the measurement of departmental prestige. Clearly, further investigation is needed here.

Equation 3 also provides additional support for the importance of departmen-

tal prestige in the allocation of academic positions to graduates, and the lack of importance of scientific productivity in this process. The effect of departmental prestige increased, as did the coefficients for the mentor's citations, departmental enrollment and undergraduate selectivity. The already small coefficients for productivity were reduced even further.

Hagstrom and Hargens (1968) have suggested that much of the association between doctoral prestige and the prestige of the first job may be accounted for by the phenomenon of inbreeding. When those scientists whose doctoral and first teaching institution were the same (i.e., inbred scientists) were excluded from their analysis, the effect of doctoral prestige on first job prestige was approximately halved. Besides inflating the effect of doctoral prestige, the inclusion of inbred scientists may attenuate the effect of preemployment productivity. This would follow if productivity were more important in the placing of scientists who are not inbred than for inbred scientists for whom particularistic factors are very likely to be operating. The inclusion of inbred scientists in Equations 1 through 3 of Table 1 might, then, contribute to the lack of importance of productivity. In Equation 4 the 52 biochemists who were inbred were excluded. The effect of doctoral prestige fell by only about 20% (compared with 50% for Hagstrom and Hargens), while the effects of productivity remained trivial and unchanged. The difference between these two studies in the effect of doctoral prestige appears to be the result of including enrollments in Equation 4. When this variable is omitted from the equation for noninbred scientists, the standardized coefficient for doctoral prestige falls from .34 to .15. The only variable whose effect has greatly changed is the mentor's citation level. When inbred scientists are excluded, the effect of the mentor is reduced and loses statistical significance, suggesting a process by which prestigious mentors at prestigious institutions seek to retain their students after they obtain a doctorate.

Postdoctoral training. For 65% of the sample, the first teaching job did not immediately follow the Ph.D., but was pre-

ceded by one or more years of postdoctoral research training. Fifty-eight percent of these individuals had job titles such as "postdoctoral fellow" or "trainee," while the remainder simply held brief positions as a research associate or a similar title. We have been unable to detect any differences in the career patterns of these two groups of postdoctoral appointees and accordingly have followed the prevailing practice of not distinguishing between "fellows" and those with "fellow-like" positions (Curtis, 1969:44). Hereafter, both groups will be referred to as fellows or postdoctorals.

It is reasonable to expect that holding a postdoctoral position should make some difference in how biochemists obtain their first teaching position. First, the mere passage of time and change of location should weaken ties with the doctoral institution while providing new social ties in the postdoctoral institution. Second, it may be argued that productivity is not important in the placement of new doctorates because they have not yet had the time to establish themselves as researchers. The postdoctoral fellowship provides the young scientist with additional time to demonstrate his or her competence through additional publications. On average, postdoctorals in our sample began their first teaching positions two and one-half years after the doctorate, with 46% having positions lasting three or more years. Finally, the additional research training received by fellows presumably should increase their desirability to academic employers in research intensive locations, resulting in a higher destination prestige for postdoctorals than for those without such advanced training (cf. Curtis, 1969:69-70).

For the most part, these expectations were not strongly supported by the data. When a dummy variable for postdoctoral position was added to the baseline model, it was found that fellows obtained positions only about 17 points higher on the prestige scale than nonfellows, net of other variables. The difference, however, was not statistically significant. An analysis of covariance (not shown) was then performed to determine if the effects of other variables in the model differed for

postdoctorals and nonpostdoctorals. Although, as expected, the effects were somewhat attenuated for the postdoctorals, none of the differences was statistically significant.

What is especially important about these null results is that even though postdoctorals have substantially more publications and citations than nonpostdoctorals, no effect of productivity on destination prestige is found. Fellows averaged 3.1 publications and 16.0 citations for the three-year period before the receipt of their first teaching position, compared with 2.1 publications and 9.0 citations for nonfellows. Even when all publications from two years before the doctorate until the year of the job were included in the regression for fellows, no effects of publications or citations were found. Clearly, the absence of productivity effects cannot be explained by insufficient time to publish.

It appears, then, that merely holding a postdoctoral position does not greatly affect one's entry into the academic career. There is evidence, however, that *where* one held such a position does make a difference. Seventy-six percent of the fellows were located in rated graduate departments, 17% were in prestigious locations other than United States graduate institutions (e.g., N.I.H., Cambridge University, Brookhaven National Laboratories), while the remaining 8% were located in either industrial laboratories or nongraduate educational institutions. After excluding nonfellows from the analysis, dummy variables indicating the type of location of the fellowship were added to the baseline model, yielding the results presented in Equation 1 of Table 2. Net of other variables, the destination prestige of low prestige fellows is nearly 60 points lower than that of fellows in rated departments. Those in prestigious locations, but not American graduate departments, also did worse but the difference was slight and not statistically significant.

By restricting the analysis to postdoctorals in rated departments, the effect of the prestige rating of the postdoctoral location could be added to the baseline model. Equations 3 and 4 of

Table 2 show that postdoctoral prestige is clearly the best predictor of the destination prestige, while the effect of the doctoral prestige is much reduced and no longer statistically significant. It is as if hiring departments pay attention only to an applicant's current position and disregard his previous institutional affiliation. Nevertheless, since doctoral prestige and postdoctoral prestige are moderately correlated ($r=.37$), the sum of the direct and indirect effects of doctoral prestige is not substantially reduced. Thus, to a certain extent, postdoctoral prestige mediates the effect of doctoral prestige. On the other hand, the results suggest that the fellowship is valuable in overcoming the negative influences of a doctorate from a low prestige institution.

Postdoctorals not only obtain a new location from which to launch their careers, but also a new mentor with whom they may work even more closely. Unfortunately, the names of these mentors are unavailable. We suspect that the inclusion of their citation level in the model would further reduce the effects of both doctoral prestige and the dissertation supervisor's citation level.

Overall, then, we may conclude that while postdoctorals as a group do not do much better in prestige attainments than nonpostdoctorals, the prestige of their postdoctoral position becomes the key determinant of the prestige of their first job. Further, even though fellows have had greater time in which to demonstrate their ability as researchers and have published significantly more papers, the effect of productivity on the prestige of their first teaching position remains statistically insignificant.

Academic rank. A final variable which should be considered is the academic rank of the first job. The trade-off between the cosmopolitan reward of position in a prestigious department and the local reward of high academic rank was discussed by Caplow and McGee (1958) who noted that downward mobility in the prestige hierarchy was almost always accompanied by advancement in academic rank. Hargens (as quoted by Cole and Cole, 1973:260) found a similar phenomenon in a larger sample of scientists. To incorporate

this trade-off between rank and prestige into our model of the allocation of the initial teaching position, the independent variable of the academic rank of the first position was added.³ The results of this addition are presented in Equations 2 and 5 of Table 2. It proves to be an important variable, decreasing the expected prestige of the first job by approximately 40 points for every advancement in rank. When rank was included in the regression for all 239 biochemists (regression not shown), the effect was halved, although still significant, reflecting the lesser variation in the rank of the first position among non-fellows.

ASSESSING UNIVERSALISM

Let us summarize the results to this point. The principal determinant of the prestige of a biochemist's first teaching job is the prestige of his most recent departmental affiliation, with somewhat weaker effects of mentor's prestige and the selectivity of the undergraduate institution. A negative effect of the size of graduate enrollment in the doctoral department also is found, along with substantial differences among individual de-

partments which are unattributable to either their prestige or their enrollment. For fellows, there is a trade-off between academic rank and the prestige of the position accepted. In no case is an effect of preemployment productivity found.

These results are combined in the augmented model shown in Table 3. This regression differs from that in Equation 2 of Table 1 by the addition of a variable which is the prestige of the postdoctoral department for all those who held postdoctoral positions in rated departments.⁴ As before, doctoral prestige has the strongest effect, followed by postdoctoral prestige and doctoral enrollment. Mentor's citations and undergraduate selectivity have effects which are positive and marginally significant. The effects of publications and citations, however, are far from statistically significant.

Taken alone, these results do not tell us much about the observance of the norm of universalism in science. Certainly the absence of any productivity effects runs contrary to an extreme interpretation of universalism which would require that

³ Academic rank was coded as follows: 4=instructor; 5=assistant professor; 6=associate professor; 7=full professor. To determine the effects of this arbitrarily chosen metric, we also used a series of dummy variables to determine the effect of rank. The results were similar.

⁴ For biochemists who did not hold a postdoctoral position in rated graduate departments, this variable was assigned a value of 358, the mean for those who did not hold such positions. Also included in the equation was a dummy variable coded 1 if the individual did hold a postdoctoral position in a rated graduate department, otherwise 0. The coefficient for this variable has no substantive interpretation; it is included only to make the model invariant to the particular value (in this case 358) assigned to those cases without a postdoctoral prestige score.

positional prestige be allocated only on the basis of past scientific contributions. But it is much more reasonable, and surely in keeping with Merton's notion of universalism, to expect departments to choose among new doctorates on the basis of their anticipated contributions. It is conceivable that preemployment productivity might actually be a very poor predictor of future productivity, while such variables as doctoral prestige and mentor's citations might be quite good indicators. Clearly departments which want doctorates who will be productive researchers should rationally base their choice on those variables which are known to be good predictors, not on some *a priori* distinction between universalistic and particularistic criteria.

Fortunately it is not necessary to speculate about the relative power of these variables in predicting future productivity. For our sample, future productivity was measured by the number of articles published in the fourth through sixth years after the receipt of the position and by the number of citations these publications received in the sixth year. These measures of future productivity were regressed on the variables considered thus far, restricting the analysis to the 134 biochemists who remained in the same department for at least six years. This restricted sample was necessary since earlier research (Long, 1978) has presented evidence for the importance of departmental location on productivity, a point to be examined below. The results are presented in Table 4.

The future level of publication is most strongly influenced by predoctoral publications as indicated by the strong and statistically significant standardized regression coefficient in Equation 1. The effects of doctoral prestige, postdoctoral prestige for fellows, the mentor's level of citations, and undergraduate selectivity are all positive, but their magnitudes are small and not statistically significant. It appears that those who publish early in their careers continue to publish, but that having a distinguished pedigree does not significantly affect future publication levels.

Doctoral origins appear to be far more

important in the determination of future citation levels. Equation 2 indicates that the prestige of the doctoral department along with the size of that department are the most important factors predicting future citations. The effect of prestige is strong and positive while the effect of enrollment is strong and negative; both effects are statistically significant. The effects of preemployment productivity are both positive and statistically significant, albeit slightly weaker than the effects of doctoral characteristics. The mentor's prestige and the selectivity of the undergraduate institution have insignificant effects. These results suggest that doctoral prestige may be useful as an indicator of future citation levels of job candidates, but that preemployment productivity also should be considered.

These results, while accurate as far as they go, do not adequately reflect the causal mechanism involved in the effect of origin on future productivity. As Long (1978) has shown in similar analyses for the same sample, departmental location of employment is an important factor in determining scientific productivity. This is reflected in Equations 3 and 4 in which the prestige of the current employer is added to the earlier equations. The results suggest quite a different story. Much of the effect of the origin department is not direct, but rather operates indirectly through the effect of origin prestige on the first job. Thus, origin prestige influences the prestige of the first job, and the prestige of the first job influences the productivity of the scientist while he holds that job. For publications, the prestige of the current employer is the second strongest factor, behind preemployment publications; the effects of all other variables are reduced and statistically insignificant. For citations, the effect of current prestige is the strongest factor, followed by the statistically significant effect of earlier publications. The effects of doctoral characteristics are greatly reduced and are no longer statistically significant.

The absence of any effect of the mentor's level of citations and the selectivity of the baccalaureate institution is a strong indication that using them as criteria for

awarding prestigious jobs is inconsistent with the principle of universalism. Similarly, the strong effect of preemployment productivity on later productivity suggests that departments are being nonmeritocratic in ignoring these variables in their hiring decisions. While doctoral characteristics have a strong effect on future citations when departmental location is not controlled for, our results suggest that this is the result of the particularistic effect of doctoral prestige on the allocation of the first job and the subsequent effect of departmental location on future productivity. Thus, rather than giving support for the use of doctoral characteristics as valid indicators of future productivity, it suggests the operation of cumulative advantage (cf. Allison and Stewart, 1974). After controlling for departmental location, the effect of doctoral prestige on future citations is still positive and marginally significant, but this is a weak defense of universalism.

Finally, the possibility that hiring departments made effective use of information concerning specific doctoral departments which we have not been able to measure was considered. Recall that significant differences among departments in the prestige attainments of their students were found that were unattributable to the prestige of the department. One possible explanation is that, apart from prestige, some departments were simply more effective than others in training or recruiting students with high research potential and that these differences were perceived by hiring departments. The evidence does not favor this explanation. When dummy variables for the 20 schools with the most biochemistry doctorates were entered into Equations 3 and 4 of Table 4 (regressions not shown), there was no significant increment in the R^2 . Thus, characteristics other than prestige and enrollment were not associated with differences in future research productivity.

SUMMARY AND CONCLUSIONS

The basic result with which this paper was begun has hardly been altered by the

preceding analysis: there is a substantial correlation between the prestige of scientists' doctoral departments and the prestige of their employing departments, and this relationship cannot be explained by any other variable that we have measured. In particular, it is not a consequence of the greater productivity of students from prestigious departments or of the fact that those from more prestigious departments have more prestigious mentors (an explanation suggested by Cole and Cole, 1973:117). For those who take postdoctoral training positions, the prestige of the postdoctoral institution replaces doctoral prestige as the key determinant of the prestige of the first teaching position. Besides this unexplained prestige effect, larger departments were found to do worse in placing their students net of other factors; moreover, there are significant differences among departments in the prestige attainments of their students which are not attributable to their prestige or enrollment.

To settle the question of whether the influence of doctoral prestige reflects universalistic or particularistic hiring practices, it is first necessary to determine whether doctoral prestige is a good predictor of later productivity. We have shown that it has only a modest effect on citation counts six years into the first job and virtually none on publications. But this result is overshadowed by the fact that preemployment productivity is a much better predictor of later productivity than doctoral prestige, either alone or in combination with other variables in this study. Yet, hiring departments seem to ignore completely this most obvious predictor of future productivity.

All of this seems to support the impressionistic conclusion of Caplow and McGee (1958) that hiring departments pay attention only to where a candidate comes from and who recommends him, while virtually ignoring written work, either published or unpublished. While the apparent effect of doctoral prestige on later productivity suggests that this process may not be entirely inconsistent with the meritocratic principle, we suspect that it is more accidental than deliberate. As evi-

dence for that interpretation, we note that for fellows it is the postdoctoral prestige that has the principal effect on first job prestige even though postdoctoral prestige has no independent effect on later productivity. It therefore appears that departments rely on current affiliation irrespective of any predictive validity for research productivity.

Although these results are for a single scientific field, we see nothing peculiar about biochemistry that would raise doubts about their generalizability. Biochemistry does have one of the highest percentages of students who take postdoctoral research positions (Curtis, 1969), but we have shown that there is little difference between those who do and those who do not take such positions. Biochemistry also tends to be split between an agricultural and a medical orientation, and we have shown elsewhere that those who get degrees from a medical or arts college are far more likely to get postdoctoral fellowships than those from agricultural colleges (McGinnis et al., 1979). Still, we have found no significant differences between these groups in the effects of other variables on the prestige of the first job.

It may be argued that the first job is not a good site for observing universalism in science since information about job candidates is relatively poor and, hence, particularistic factors are bound to creep in. We have shown, however, that departments do not make good use even of that information which is readily available to them, namely, the number of articles a candidate has published, and for fellows this represents the results of a significant period of research. Moreover, whether or not the allocation of initial employment is typical of decision making in other areas of science, the fact that so many scientists stay in that first position means there is only limited opportunity to correct mistakes. Finally, Long (1978) has shown that past productivity has little effect on the destination prestige of those who change jobs later in their careers. His sample size is small, however, and we are currently undertaking a much larger study of mid-career job changes.

RESEARCH NOTES

CHANGES IN THE SEX ROLE ATTITUDES OF WOMEN, 1962-1977: EVIDENCE FROM A PANEL STUDY*

ARLAND THORNTON
University of Michigan

DEBORAH FREEDMAN
University of Michigan

American Sociological Review 1979, Vol. 44 (October):831-842

This paper documents a tremendous shift women have made towards more egalitarian sex role attitudes between 1962 and 1977. The shift toward egalitarianism was considerably more pronounced for the global items concerned with the general principles of role segregation and division of authority within the home than for more specific aspects of role specialization, such as the sharing of housework or the legitimacy of nonhome activities for mothers. In 1962 sex role attitudes bore no appreciable relation to a wide spectrum of individual characteristics. By 1977 many of these basic characteristics were related to sex role attitudes. Younger women, those with more education, those with better educated husbands, and those who were working in 1962 were more likely than others to adopt egalitarian sex role attitudes, while mothers of large families and fundamentalist Protestants tended to retain traditional attitudes. The experience of the women during the 1962 to 1977 intersurvey period also was associated with a shift in sex role attitudes. Additional education, work for pay, and exposure to divorce were associated with shifts toward egalitarian attitudes while additional births were associated with retaining traditional attitudes.

Introduction

Important changes have occurred both in family life and in the distribution of occupational roles in the United States. While men continue to specialize primarily in occupational roles outside the home, married women increasingly combine paid employment with traditional homemaker roles. The divorce rate has increased dramatically, fertility has declined sharply, age at marriage has risen, and there has been a general increase in edu-

cational attainment. Meanwhile, the women's movement has focused attention on the sex-based assignment of tasks, authority, and status with the goals of changing attitudes and providing a wider range of opportunities for women. A growing body of empirical evidence indicates that these changes have been accompanied by a general and pervasive shift in beliefs and values concerning appropriate roles for women (Bayer, 1975; Boyd, 1974; Erskine, 1970; Ferree, 1974; Mason et al., 1976; Monteiro, 1978; Parnes et al., 1975; Schreiber, 1978; Suter and Waite, 1975; Waite, 1978; also see Smuts, 1959 and Oppenheimer, 1970).

Although several cross-section studies have demonstrated that sex role attitudes differ across various groups in the population (Dowdall, 1974; Mason and Bumpass, 1975; Mason et al., 1976; Scanzoni, 1975; Shea et al., 1970; Thornton and Camburn, 1979; Waite and Stolzenberg, 1976), the extent to which changes in sex role attitudes have been uniform and pervasive across these various groups is not well understood. It also is not clear to what extent changes in sex role attitudes

The data used in this paper were collected as part of a five-wave longitudinal study with the first four waves being collected under the direction of Ronald Freedman, David Goldberg, and Lolagene Coombs. The authors wish to thank those individuals for their contribution to this research. The fifth wave of interviews and the analysis reported here were supported by NICHD Grant HD-10407. The authors also acknowledge the contribution of the interviewing and coding staffs at the Survey Research Center and the computer staffs at the Survey Research Center and Population Studies Center, University of Michigan. Donald Camburn provided expert assistance during all stages of this project.

are associated with going back to school, going to work, bearing children, or experiencing a divorce, since the previous studies have used either cross-sectional data or panel data extending over relatively short time intervals (Angrist and Almquist, 1975; Ferber, 1977; Kim et al., 1973; Parelius, 1975; Spitze, 1978; Spitze and Waite, 1978). The research reported in this paper investigated the extent and nature of changes in sex role attitudes during a 15-year period of extensive change—1962 to 1977. The data, having been collected from the same women in 1962 and 1977, were particularly appropriate for this investigation.

Data

The data used for this research were collected between 1962 and 1977 from a sample of white women living in the Detroit metropolitan area who either had just married or had just had a first, second, or fourth birth. Approximately equal numbers of first, second, and fourth parity women and a somewhat smaller number of just-married women were sampled. Within strata, the women were chosen by simple random sampling from the birth and marriage records of the Detroit area. An initial personal interview, conducted during the winter of 1962 was followed by four telephone interviews—in the fall of 1962, in 1963, 1966, and 1977.

The response rates, both in the initial interview and follow-ups were excellent. During the first wave of the study, interviews were obtained from 1,304 women, representing a response rate of 92%. Of those 1,304 original respondents, full interviews were obtained in 1977 with 1,161 or 89%. A comparison of the 1977 sample with the original 1962 respondents indicated that the overall characteristics of the 1977 group were only slightly different from those of the original sample.

In the 1962 and 1977 interviews respondents were asked to respond to the following series of statements concerning the appropriate division of labor or authority between men and women.

Now, I would like to get your opinion on some matters concerning family life. I will

read you some statements, and I would like you to tell me if you strongly agree, agree, disagree, or strongly disagree. The first is:

1. Most of the important decisions in the life of the family should be made by the man of the house [Decisions].

2. It's perfectly alright [*sic*] for women to be very active in clubs, politics, and other outside activities before the children are grown up [Women Active].

3. A wife shouldn't expect her husband to help around the house after he's come home from a hard day's work [Housework].

4. There is some work that is men's and some that is women's, and they shouldn't be doing each other's [Men's/Women's Work].

Although the respondents were asked to respond in terms of one of the four agree-disagree categories, the few who insisted that they were undecided, did not know, or that "it depends" were coded into a fifth category.¹

The first question, measuring attitudes toward the division of authority and decision making in the family, indicated the extent to which the respondent supported the traditional notion that men should have more authority in the making of family decisions. The other three questions reflected attitudes toward the division of family and occupational roles between men and women. They indicated appropriate behavior for women (Women Active), for men (Housework), or for both men and women (Men's/Women's Work), and all referred to the appropriateness of the separation and segregation of roles by sex.

¹ The same questions were asked during the 1962 personal interview and the 1977 telephone interview. However, since it is more difficult in a telephone interview to sense whether the respondent fully understands the questions, it seemed advisable to make two minor modifications to clarify the questions and the prescribed response categories. First, as part of the first statement about family decision making, the interviewer repeated the phrase from the introductory paragraph: "Would you say you strongly agree, agree, disagree, or strongly disagree?" Second, in the third and fourth statements the contraction "shouldn't" was changed to "should not." It is our opinion that these changes did not affect the meaning of the questions nor the response pattern, but served to make the stimulus provided by the telephone interview closer to that provided in the original personal interview. The percentage giving do not know or depends responses varied from 1 to 7% in 1962 and from 2 to 11% in 1977.

Changes in Levels

Table 1 shows the distribution of responses for the four sex role attitude items for both 1962 and 1977. The first bank of numbers indicates the percentage giving a nontraditional response. These numbers were estimated by classifying as nontraditional or egalitarian all respondents who either agreed or strongly agreed with the nontraditionally worded item (Women Active) and all those who disagreed with the traditionally worded items (Decisions, Men's/Women's Work, Housework). All others, including those giving do not know responses, were coded as traditional or conservative, thus collapsing the spectrum of responses into a dichotomy. For the second bank of numbers the entire distribution from strongly agree to strongly disagree was ordered on a five-point scale with undecided and do not know responses being assigned a middle value of three. All items were ordered so that a high score indicated an egalitarian response while a low score indicated a traditional orientation. In addition, a summary index was created by adding together the four individual questions.

Table 1 clearly demonstrates a shift toward egalitarian sex role attitudes between 1962 and 1977. The percentage giving a nontraditional response in 1962 ranged from 32 to 56%. By 1977, these percentages had increased between 16 and 35 percentage points, with 60 to 77% of the women giving liberal responses at that time (cols. 1 to 3 of Table 1). The changes in the mean scores (cols. 5 and 6 of Table 1) also indicate a substantial increase in nontraditional orientations during the 15 years. In fact, the increases in means (col. 7) amounted to .43 to .81 standard deviations, reflecting considerable change during this 15-year period.

Although all the attitudes shifted toward egalitarianism during the 15 years, the magnitude of the increases varied. The largest change occurred for Decisions; the percentage giving a liberal response increased by 35 percentage points (from 32 to 67%) while the mean increased by .99 (from 2.52 to 3.51). Next largest was the change in Men's/Women's Work where the nontraditional response increased by 22 percentage points for the dichotomy and .67 on the five-point scale. The in-

Table 1. Distribution of Sex Role Attitudes: 1962 and 1977

Number of Respondents: 1158.

^a Respondents agreeing or strongly agreeing with Women Active or disagreeing or strongly disagreeing with Decisions, Housework, and Men's/Women's Work were coded as nontraditional. All others, including those giving do not know responses were coded as traditional.

^b Responses were coded on a five-point scale from one to five with a high score indicating a nontraditional response and a low score a traditional response. For Sex Role Index, the four single items were summed together.

^c (1977 percentage - 1962 percentage) ÷ (100 - 1962 percentage).

^d (1977 mean - 1962 mean) ÷ (5 - 1962 mean).

^e The 1977 standard deviations were quite similar to those in 1962.

crease for the other two questions was somewhat lower, though still substantial.

Of course, the extent of the possible shift towards egalitarianism depends partly on the degree of traditionalism in 1962; the more traditional the 1962 attitudes, the greater the possible change. Columns 4 and 8 of Table 1 list the 1962 to 1977 change relative to the amount of change possible, given the 1962 distribution. From this perspective, Decisions and Men's/Women's Work changed considerably more than did Women Active and Housework. Similar results were obtained when the changes in mean scores were compared with the 1962 deviations. Again, the relative shifts for Men's/Women's Work and Decisions were considerably more pronounced than for the other two items, with the change for Decisions being almost as large as its standard deviation.

How can these differential shifts be explained? These data show more movement towards rejection of sex segregation as a general principle than towards rejection of specific forms of segregation. Apparently the impetus of the change has been directed more towards general and global orientations than toward specific aspects of role specialization. Although these women increasingly have rejected the general principle that men should have more prerogatives than women, their experience within the family and with the practical aspects of allocating household work may have mediated their thinking about specific activities. This speculation is based on the fact that Men's/Women's Work is a strong statement legitimizing the general principle of segregation of men's and women's roles while Decisions strikes at the heart of who runs the house—whether or not that is the man's prerogative. The other two attitudes, Women Active and Housework, refer to very specific activities of men and women with which the respondents have had considerable practical experience. Confidence in this distinction between general and specific attitudes is buttressed by other research (Boyd, 1974; Monteiro, 1978) which has found a greater degree of change in general orientations than in more specific sex role attitudes.

Subgroup Differences in 1962

Table 2 shows the relationships between the 1962 sex role attitude summary index² and several of the 1962 background characteristics, including the respondent's education, age, religion, employment experience, and parity as well as her husband's education and 1961 income. Both zero-order or unadjusted relationships and relationships adjusted by Multiple Classification Analysis (MCA), a form of dummy variable regression (Andrews et al., 1973)³ are shown.

Overall, the relationships between the 1962 sex role attitudes and the background characteristics were either small or

² A preliminary analysis which investigated the possibility of the four individual sex role items being indicators of one underlying construct showed that no simple model adequately could account for the observed pattern of relationships between the four individual variables. Therefore, the analysis investigated the relationships between the independent variables and sex role attitudes separately for the four individual variables rather than using the four variables as indicators of an underlying unmeasured concept. Nevertheless, the relationships between the independent variables and the four individual sex role items were sufficiently similar that the relationships for the summary index adequately represented the patterns for the four individual variables. To simplify the presentation of results, we present only summary index data in Tables 2 and 3, but where variations exist in the pattern of relationships for particular sex role items, these differences are noted in the text.

³ While it would have been possible to conduct the analysis using ordinary multiple regression, the use of ordinary regression would have necessitated the use of a considerable number of dummy variables since several of the explanatory variables were measured at the categorical rather than interval level. Therefore, it was decided to convert all of the explanatory variables to a nominal level and use MCA. MCA also has the advantage of allowing for nonlinearities in functional form. In the tables Eta square (E^2) is the zero-order correlation ratio, showing the amount of variance in the dependent variable (sex role attitude) explained by each independent variable before adjusting for any other variable. Beta square (B^2) is analogous to eta square but reflects the adjustments of the multivariate analysis. While eta square is the percentage reduction in variation accomplished by measuring variation around the unadjusted subgroup means rather than around the overall or grand mean for that dependent variable, beta square indicates the reduction that would occur if variation were measured around the adjusted means rather than the overall or grand mean (see Andrews et al., 1973).

^a The adjusted means were obtained from an MCA equation including all of the variables listed above. The mean for the total sample was 11.36.

^b For the rows labelled E² or B², the E² figure is noted in the Unadjusted columns, while B² is noted in the Adjusted columns.

nonexistent. Both the differences in the means (unadjusted and adjusted) and the amount of variance in the sex role atti-

tudes accounted for by the independent variables support this conclusion.

While the overall relationships in 1962 were meager, a few differences are noted. There was a small relationship between the respondent's education and 1962 attitudes, with the better educated having somewhat more egalitarian attitudes. The very young women were substantially more traditional than others. This may reflect the restriction of our sample to married women since those marrying young probably are drawn disproportionately from those with more traditional attitudes. The only noticeable and consistent religious differential was between Jewish women and all others, with Jewish women being more egalitarian. Contrary to expectations, there was a small positive association between parity and nontraditional attitudes. While the childless women were the most traditional on every measure, the largest positive association between parity and egalitarian attitudes was for the Housework and Men's/Women's Work items which may reflect the fact that women with large families have more demands on their time and may need more assistance from their husbands. Finally, women who were working at the time of the 1962 interview were the most egalitarian, while those who had never worked or who had worked only before marriage were the most traditional.

Attitudinal Change between 1962 and 1977: Which Groups Were Affected?

Table 1 documents a substantial increase in egalitarian sex role attitudes between 1962 and 1977—an increase of 2.71 points on the sex role attitude summary index for the total sample. A more detailed analysis investigated whether or not this change was pervasive across various subgroups of the population or was limited to particular groups. Two sets of variables were used to define subgroups. The first set included the group of characteristics measured in 1962 and examined earlier in Table 2. The second set included the following experiences of the women between 1962 and 1977: a crude index of the amount of time worked during the intersurvey period; the number of children

born; whether or not the woman had obtained any additional education⁴ during those years; and her 15-year marital history—including experience, if any, with divorce, widowhood, and remarriage. This analysis indicates that the change shown in Table 1 was very pervasive; every group examined registered increases in egalitarianism (data not shown).

While all of the subgroups experienced increases in egalitarianism, there were important differences in the amount of change. The analysis of subgroup differences used three different models as documented in Table 3. In Model 1, a series of MCA equations were estimated with the 1977 summary index as the dependent variable and the 1962 summary index and a *single* explanatory variable as the independent variables. For the subgroups of each explanatory variable, the deviations from the overall 1977 mean were estimated adjusting for the 1962 attitudes of each subgroup. Since the 1962 sex role index was included in each equation along with the specific explanatory variable, these deviations represent the difference between the amount of change for each particular subgroup and the average change in attitudes for the entire sample which was 2.71. Thus, with the 1962 index controlled, subgroup deviations represent differential change during the intersurvey period associated with particular characteristics.⁵

In the second and third models, MCA equations were estimated with the 1977 sex role index as the dependent variable and the 1962 index and *several* explanatory variables as the independent variables. In Model 2 the 1962 characteristics were included as explanatory variables while both the 1962 characteristics and the intersurvey experiences were included in Model 3. Thus, Model 2 shows the extent to which each 1962 subgroup changed differentially net of the influence of all

⁴ This includes skill training but not domestic classes like sewing and cooking.

⁵ An alternative approach would have been to use the difference between 1977 and 1962 sex role attitudes as the dependent variable. This approach, however, would have created a negative correlation between 1962 attitude and change between 1962 and 1977—a compelling disadvantage.

* All numbers shown in the table were estimated using MCA equations with 1977 sex role attitudes as the dependent variable. The Model 1 deviations were estimated from multiple MCA equations with the specific explanatory variable in question and the 1962 sex role attitude summary index as independent variables. The Model 2 deviations were estimated using an MCA equation containing all of the 1962 background variables and 1962 sex role attitudes as independent variables. In Model 3 the variables representing intersurvey experiences were added to the equation used in Model 2. Since 1962 sex role attitudes were included in all of the equations, thereby taking them into account, the results should be interpreted as reflecting subgroup differences in change between 1962 and 1977 rather than showing subgroup differences in 1977 attitudes. All numbers in the table represent the extent to which each subgroup deviated from the change for the total sample (subgroup change minus total group change). Only B² values (instead of both E² and B²) are reported since all values were estimated using MCA equations.

other 1962 variables. Model 3, which incorporates intersurvey experience, will be discussed later in the paper.

Looking first at wife's education, we noted substantial differences in change across educational groups (Table 3). The

difference between the Model 1 deviations for the least and most educated groups was 2.62—a considerable difference, given that the 1962 standard deviation of the summary index was 2.69. In addition, there were considerable differences between the Model 2 deviations, which take into account the other 1962 variables in the multivariate analysis. The positive association between education and the amount of change could reflect the access of well educated women to economically and psychologically rewarding jobs which encourage both participation in the labor force and the development of egalitarian attitudes. In addition, well educated men and women probably have constituted the biggest audience for the recent upsurge in publicity about sex roles (Cancian, 1975; Schreiber, 1978).

There also was a positive relationship between husband's education and sex role attitude change. The women with educated husbands were more likely than others to adopt egalitarian attitudes between 1962 and 1977. This correlation between husband's education and attitudinal change can not be attributed to the intercorrelation between husband's and wife's educations since the wife's education was controlled in the analysis.

The age differences in change between 1962 and 1977 were substantial, with younger women changing more than others. In fact, the youngest group of women (15-19), the most traditional in 1962, changed enough during the 15 years so that by 1977 they (together with the second youngest age group) were the least traditional. The Model 2 deviations, which adjusted for other 1962 characteristics, show an even larger negative relationship between age and change. Apparently young women are more amenable to adopting new roles and attitudes during periods of change. This may occur because they have had less socialization and experience in traditional roles and are faced with making life-time decisions about work and family. Older women, on the other hand, probably are more thoroughly socialized to accept traditional role proscriptions and, having made a considerable investment in traditional patterns, are less motivated to reexamine their defi-

nitions and beliefs during a period of change.

In observing trends over time in a panel study, it is useful to consider if the changes occurred because the times and conditions changed or because the panel members grew older, with later life stages being associated with different attitudes. While it is very difficult to separate cohort, aging, and time effects, these data provide some insights. If the change between 1962 and 1977 had been the result of the women becoming 15 years older, one would expect the older women to be the most liberal in both years. However, age was not positively related to egalitarian attitudes in 1962, and the relationship was negative in 1977. These observations give credence to the hypothesis that the aggregate changes associated with age were due to time changes rather than to maturational effects. Further support comes from previously cited research studies which, using data from multiple cross sections with similar age compositions, found substantial changes over time in sex role attitudes.

Attitudinal shifts between 1962 and 1977 did not affect all religious groups equally. The fundamentalist Protestants exhibited the most distinctive pattern. While their attitudes were very similar to those of other women in 1962, their attitudes subsequently diverged markedly so that by 1977 they had the lowest score. The difference between this group and each of the other religious groups in the amount of change on the summary index ranged from 1.01 to 1.37 (Model 2, Table 3)—considerable differences when compared with the standard deviation (2.69) of the summary index in 1962. Thus, fundamentalist Protestants appear to have taken a more conservative and traditional approach to changing sex roles than others (also see Brady and Tedin, 1976).

Only one other notable change pattern was associated with religion, a differential shift among Jewish women almost entirely attributable to their change on the decision-making item. By 1977 virtually all of the Jewish women disagreed with the statement that the important decisions of the family should be made by the man of the house. For the other attitudinal

items, Jewish women still tended to be egalitarian, as in 1962, but their degree of change was not marked.

As expected, the women with larger families in 1962 changed less during the 15 years between 1962 and 1977 than did others (Model 1, Table 3). However, the inclusion of other variables, particularly age and education in the Model 2 analysis, greatly altered the observed differences, with the relationship becoming small and somewhat U-shaped. Apparently, the higher parity women experienced less change primarily because they were older and less educated. However, one important exception was that mothers with large families in 1962 changed less on the Women Active item even with controls for other variables (results not shown). Having many children appears to inhibit the adoption of liberal attitudes toward women's outside activities.

For 1962 work experience, the only important difference in attitudinal change was between those who were working in 1962 as against all others.

Husband's 1961 income was not monotonically related to attitudinal change. Instead, a slight U-shaped relationship was apparent in the amount of change between 1962 and 1977. Several different proxies of family financial status and well-being were investigated, including husband's relative income (actual divided by expected income as based on occupation, education, and age), the wife's evaluation of the sufficiency of his income, and 1962 assets. None of these measures displayed a substantial relationship with either 1962 attitudes or change between 1962 and 1977 (results not shown).

Intersurvey Experiences: Their Relationship to Attitudinal Change

In the Model 3 analysis of differential change between 1962 and 1977 (Table 3), the four intersurvey experiences—work, childbearing, additional education, and marital experience—were included in the multivariate analysis along with the variables measured as of 1962. The inclusion of the intersurvey experiences permitted an investigation of the extent to which

they were related to attitude change during the same period. In addition, the Model 3 analysis permitted the examination of the degree to which the differential changes in attitudes for the various 1962 subgroups were the result of the differing experiences of these groups with regard to working, education, fertility, and marital disruption between 1962 and 1977.

Intersurvey experience with labor force participation, additional education, and marital disruption were all associated with shifts towards egalitarian sex role attitudes (Model 3, Table 3). As expected, women who acquired additional education and those with more years of work shifted more towards egalitarianism than others, with fairly sizeable differences. Since it was expected that job status and job quality also might be related positively to attitudinal change, an additional analysis incorporated these other dimensions of work experience. However, attitudinal change correlated more with the amount of work than with the prestige of the job (measured by Duncan SES scores) while variables which combined both the prestige dimension and the number of hours worked produced only slightly higher correlations than those obtained with hours of work alone. Labor force participation appears to foster nontraditional attitudes by providing experience outside the home with its accompanying exposure to egalitarian ideas. Nonhome experience appears to be the important labor force correlate with attitudinal change rather than the nature of the particular job.

There were surprisingly small relationships between sex role attitude change and both childbearing and divorce experience. The small effects of divorce may represent an averaging of two opposite reactions by divorcees. Since divorce can be an embittering experience for a woman, it could have a radicalizing effect on her ideas about appropriate sex roles. Alternatively, the difficult financial and emotional circumstances of many divorced women could lead them to idealize traditional roles. The relatively small shift towards egalitarianism among widows is consistent with the second possibility.

Childbearing experience since 1962 was

related negatively to attitudinal change, but after controlling for 1962 characteristics and other intervening experiences, the relationships became meagre and irregular. We had expected women bearing more children to retain traditional views, which provide validation for their chosen life patterns. Perhaps their unexpected egalitarianism reflects a continuing need for help from their husbands in the home.

Note that the observations reported in Table 3 show the *net* relationship between intervening experience and attitudinal change. While there were relationships between 1962 attitudes and intervening experiences (which are beyond the scope of this paper), those associations were controlled by the inclusion of 1962 attitudes in the multivariate analysis. Therefore, the MCA data reflect associations between the intervening experiences and attitudinal change *net* of attitudinal levels in 1962.

Although the observed relationships between intervening events and attitudinal change were not due to selection on 1962 attitudes, conclusions about the direction of causality are more problematic. It is not clear if the attitudinal change caused the experiences during the 15 years or if the experiences caused the attitude change, since we do not know when the sex role attitudes changed, but only the overall differences between 1962 and 1977. A more detailed planned analysis, which takes into account plans in 1962 and the timing of the intervening experiences, should provide some insights concerning the nature of the causal forces.

Since intersurvey experience was associated with sizeable shifts toward egalitarian attitudes, an important question is the extent to which the 1962 groups became more egalitarian over time because they had such experiences between 1962 and 1977. For most of the 1962 subgroups, the answer is negative; the differential changes in attitudes were mostly independent of these intersurvey experiences. The analysis of attitudinal change between 1962 and 1977 which included all the 1962 independent variables together with the intersurvey experiential variables, produced, with some exceptions, substan-

tially the same array of adjusted deviations for the 1962 subgroups as did the similar analysis without the intersurvey experience (compare Models 2 and 3 of Table 3). Apparently, for most of the 1962 subgroups, the differential attitudinal change between 1962 and 1977 did not result from these kinds of differential experiences during the intersurvey period.

Intersurvey experience, however, did mediate the effect of age and 1962 labor force experience on attitudinal change. The correlation between age and attitudinal change was substantially smaller in Model 3, which included the intervening experiences, than in the equation excluding those variables (Model 2). Thus, one reason the younger women changed more was their greater exposure to experiences conducive to attitudinal change. A separate analysis found that the younger women were more likely than others to obtain additional education, to work more, and to have more experience with divorce. However, these experiences cannot entirely account for the differential changes between the young and old since substantial differences persisted even after adjusting for the intervening experiences (see Model 3).

The intersurvey experience variables entirely account for the relationship between work experience as of 1962 and attitudinal change between 1962 and 1977. A separate analysis showed that women working in 1962 were more likely than others to obtain additional education, to work many hours, to have few children, and to obtain a divorce during the intersurvey period. After allowing for the added effect of these intersurvey experiences, women working in 1962 experienced no more change over time than women with lesser work experience.

Summary

This paper documents the tremendous shift among women towards more egalitarian sex role attitudes between 1962 and 1977. Whereas in 1962 32 to 56% of the respondents gave egalitarian responses concerning various sex role attitudes, by 1977 these percentages ranged from 60 to 77%. This trend towards egalitarian sex

role attitudes cannot be explained by the maturation of these women; age was not related positively to egalitarian attitudes at either date. Thus, the attitudinal shift over the 15-year period reflects changing conditions between 1962 and 1977.

The shift towards egalitarianism is considerably more pronounced for the global items concerned with the general principles of role segregation and division of authority within the home, than for the more specific aspects of role specialization, such as the sharing of housework or the legitimacy of nonhome activities for mothers. One possible explanation could be that the general trend towards more egalitarian attitudes about appropriate roles for men and women becomes somewhat tempered when specific activities are concerned—activities with which these women have been involved for a considerable number of years. This group of women, aged 15–39 in 1962, had their children during the baby boom; and although most of them have worked some time during their life, only 50% have worked 2½ years or more during the past 15 years. This group, like most mothers during the baby boom, spent most of their married lives taking care of the home and children while their husbands supported the family. The realities of allocating work and home responsibilities undoubtedly have made them more aware of the problems involved in shifting responsibilities with regard to specific home tasks even though they may, in principle, support equal prerogatives for men and women as well as more equal sharing of family and occupational roles. Since the survey data showed that these women performed most of the home and child care tasks, their lesser shift on attitudes regarding specific tasks may reflect the actual sex role division within their households.

In 1962, sex role attitudes bore only slight relation to a wide spectrum of individual characteristics, including age, education, religion, number of children, work experience, husband's education, and husband's income. Many of these basic characteristics, however, were important determinants of the extent of attitudinal change between 1962 and 1977. Younger women, those with more education, those

with better educated husbands, and those who were working in 1962 were more likely than others to adopt egalitarian sex role attitudes, while mothers of large families and fundamentalist Protestants tended to retain traditional sex role attitudes. With the differential change between 1962 and 1977, many of these background variables were correlated with 1977 sex role attitudes. These data support previous research findings (Boyd, 1974; Ferree, 1974; Schreiber, 1978) that differentials in sex role attitudes across population subgroups is an emergent phenomenon. Apparently, the events of the last 15 years have both liberalized sex role attitudes and have altered their relationships with several social and demographic variables.

The experiences of the women during the 1962 to 1977 intersurvey period were associated with shifts in sex role attitudes. Additional education and paid employment were associated with a marked shift toward egalitarianism; divorce was associated with a small egalitarian shift; and additional births were correlated with retaining traditional attitudes. Although our inability to pinpoint the timing of employment, education, and changes in sex role attitudes during the interim period precludes the identification of the causal mechanisms producing the observed associations, it is likely that at least some of the relationship was caused by additional education and work influencing sex role attitude change.

While the characteristics and experiences of the women were related to the amount of attitudinal change between 1962 and 1977, they certainly did not account for the magnitude of the shift. The changes in sex role attitudes were not limited to certain groups of women, but were pervasive throughout society. The events of the past 15 years have been of such magnitude and importance that they have affected all groups of women irrespective of their experiences and characteristics.

A PANEL MODEL OF CRIME RATES AND ARREST RATES*

American Sociological Review 1979, Vol. 44 (October):843-850

In this paper, panel models for crime rates and arrest rates are utilized to separate the effect of law enforcement from several other processes that have been advanced as possible determinants of an enforcement-crime relationship. When models of this type are estimated for official index crime rates in a sample of U.S. cities for the years 1964-1970, no meaningful relationship between arrest rates and crime rates is found. This finding permits us to exclude the existence of any appreciable deterrence effect.

A decade ago, research interest in crime deterrence was revived by two studies that reported significant negative relationships between geographically aggregated crime rates for some index offenses and measures of the certainty and severity of imprisonment (Gibbs, 1968; Tittle, 1969). Since then numerous investigators have continued to interpret correlations between crime rates and various measures of law enforcement activity as evidence for the existence of a deterrent effect.¹ It is equally plausible, however, that these correlations reflect the effect of crime rates on law enforcement, or the effect of other variables on both rates.

Authors' names are listed alphabetically. We gratefully acknowledge the assistance of Betty Sheets, Walt Harrison and Andrew Rollings in carrying out the computations. Howard Erlanger, Franklin Fisher and Daniel Nagin supplied helpful comments on an earlier draft. We thank the Uniform Crime Reporting Division of the F.B.I. for supplying data on arrest rates and crime rates to Charles Logan. We are also grateful to the F.B.I. for refusing to give David Greenberg the same data, thereby making this collaboration possible. We wish to note with concern, however, the danger to scholarly inquiry posed by this sort of selectivity in the release of data by government agencies. Part of this research was funded by a grant from the Russell Sage Foundation to David Greenberg. Support was also received under Grant No. 79-NI-AX-0054 from the National Institute of Law Enforcement and Criminal Justice. Points of view are those of the authors and do not necessarily reflect the position of the U.S. Department of Justice.

¹ For a recent review of this voluminous literature see Nagin (1978).

The impact of crime on enforcement practices can come about in at least two ways. (1) Higher crime rates could tend to saturate crime control capabilities that are fixed in the short run. Thus when crime rates increase, police resources may be stretched thin, reducing the probability of an arrest following an offense. When the number of arrests increases, prosecutors and judges faced with larger caseloads may dismiss more cases and accept plea bargains more favorable to the defendant. If the number of commitments to prison leads to overcrowded prisons, parole authorities may release prisoners earlier than usual, reducing the average length of sentence served in prison. (2) Crime rates could influence enforcement through their effect on attitudes toward crime. It is possible that high crime rates create habituation to crime and hence lower penalties; on the other hand, high crime rates might tend to increase public fear of crime and thus lead to more punitive or efficient enforcement measures.

It is important to note that these two potential effects of crime on enforcement differ not only in the time span over which they are likely to be felt but, more importantly, in their signs as well. The saturation effect, which will tend to reduce enforcement efficiency as crime increases, will be felt almost at once, while the influence of the crime rate on public demand for punishment could tend to increase enforcement efficiency as crime rates rise. However, this effect will not be felt immediately, but will lag behind the crime

rate, both because public recognition generally lags behind "objective" indicators of social problems, and because it usually takes time for public concern to be translated into enforcement policy.

As for the impact of enforcement practices on crime, the period of time over which the influence is expected is uncertain. The deterrent, restraining, rehabilitative and stigmatizing effects of enforcement could all occur on both a short-term and long-term basis. Here, however, there is less reason to expect these effects to be of opposite sign.

Alternative Methods of Estimating Reciprocal Influences

All but a handful of studies of the effect of law enforcement on crime have employed cross-sectional designs; the more sophisticated of these studies have used simultaneous equation methods for separating the effect of crime on punishment from the effect of punishment on crime (Ehrlich, 1973; Greenwood and Wadychi, 1973; Mathiesen and Passell, 1976; Orsagh, 1973). However, in these analyses, lagged effects are absorbed into later measures of enforcement and crime. If these effects are of opposite sign, as we have suggested the effect of crime on enforcement is expected to be, they will tend to cancel and lead to an underestimation of the influence of crime on enforcement. To avoid this possible source of bias, a model of the effects of crime on enforcement must include both short-term and long-term effects.

A second difficulty is also inherent in this approach. To separate the two influences of the rates from one another, we must include some outside predictor variables in the model and use them as instruments, by fixing a priori the partial regression coefficients of the predictors with the criterion score at some prespecified value.² However, this proce-

sure is highly sensitive to misspecification; should these identification restrictions be in error, the estimation of effects will again be biased, perhaps grossly (Fisher and Nagin, 1978; Greenberg, 1977).

A second approach to the disentangling of reciprocal effects has been to analyze time series data for crime rates, enforcement variables, and a variety of additional variables assumed not to be influenced by crime rates or arrest rates, for a single unit of analysis, usually the entire nation (Votey and Phillips, 1974; Ehrlich, 1975; Land and Felson, 1976). This approach allows explicit consideration of both short-term and long-term effects, both of crime on enforcement and of enforcement on crime, and is therefore superior to cross-sectional analysis. Yet, since it is still necessary to make use of instrumental variables to obtain a unique solution, parameter estimates are subject to the same possible source of bias as estimates derived from cross-sectional analyses.

A third approach to the problem of reciprocal effects, which we extend below, is the use of panel models. Here data are collected for a number of spatially distributed units (e.g., cities, states) at more than one time, and the reciprocal short-term and long-term effects of crime and enforcement estimated. Thus far, all panel studies of crime rates have involved only two waves of data (Tittle and Rowe, 1974; Logan, 1975; Pontell, 1978). With this limited amount of data, however, the utility of panel models is restricted, for it is necessary to impose identification restrictions that are hardly less implausible than those required in cross-sectional and time-series models³ (Duncan, 1969).

should be made on the basis of prior knowledge concerning the causes of crime. Yet this knowledge is still primitive and uncertain. Thus any conclusions derived on the basis of such restrictions must be regarded with caution. Nagin (1978) and Fisher and Nagin (1978) have argued on the basis of their review of the literature that the restrictions which have been used to achieve identifiability are in many instances quite implausible.

³ For example, in an analysis of city crime and arrest rates in Florida for 1971 and 1972, Tittle and Rowe (1974) estimate two-wave panel models which assume that cross-instantaneous effects vanish. Logan (1975), analyzing state index offense and arrest data for the years 1964-1968, also uses two-

² In practice this is usually done by assuming that some demographic, socioeconomic or political variables are causes of punishment, but do not affect crime either directly or indirectly (except through their influence on punishment). The assumption that a given exogenous variable has an effect of specified magnitude on the crime rate (including zero effect)

* Lower case letters represent standardized regression coefficients and correlations among residuals.

Figure 1. Three Wave, Two-Variable Panel Model for Crime Rates and Clearance Rates*

A multi-wave panel model. In view of the uncertainty surrounding the assumptions necessary to identify the models reviewed above, the development of alternative methods of analysis seems warranted. Here we explore an approach that we regard as particularly promising—the use of multiwave panel models which impose assumptions about the consistency of effects rather than assume that certain effects have given values. This method permits the data to play a larger role in the analysis, and therefore seems preferable to methods that require stronger assumptions, given the limitations in our knowledge of crime causation and the duration of causal effects.

The basic ideas of the consistency procedure can be seen in Figure 1, which illustrates a three-wave, two-variable panel model. In this model, the per capita crime rate (C) at time t is assumed to de-

pend linearly on the crime rate at time $t-1$, and on the arrest clearance rate (A) at times t and $t-1$. Similarly, the current clearance rate at time t is assumed to depend linearly on the clearance rate at time $t-1$, and on the crime rates at times t and $t-1$. Thus the model includes both lagged and instantaneous reciprocal influences between the crime rate and the clearance rate. The relationship between the crime rate and the clearance rate at time 1 is taken into account but is not subjected to causal analysis. Explicit allowance is made for the possibility that the residuals for the crime rate and clearance rate at time t (U_t and V_t , respectively) are correlated.

Given our present state of knowledge, a model of this type seems highly plausible. The effect of arrests on crime should persist no more than a few years, since rational criminals will attend to recent police performance in evaluating their chances of arrest. Similarly, the effect of crime on arrests should not last longer than a few years, since increased efficiency measures, to the extent that they are influenced by earlier concern with increasing criminal activity, will probably be responsive to short-term rather than long-term concerns.

The constraints in the model consist of

wave models, and studies various specifications. In one of these, lagged effects are assumed zero; in another, only instantaneous effects of crime and only lagged effects of arrest are assumed; in a third, lagged effects of crime are assumed zero and disturbance terms are assumed uncorrelated. Although there is good overall consistency among the estimates obtained on the basis of these various specifications, the results depend on the untested assumptions of the various models.

the assumptions that the autoregressive and cross-coefficients linking the variables between times 2 and 3 are equal to those between times 1 and 2 (in the notation of Figure 1, $a_1 = a_2$, $b_1 = b_2$, etc.). A similar assumption is implied whenever an equation estimated for one time period is used to predict a crime rate or an arrest rate at a later period. With the assumption that these coefficients remain constant, this particular model is overidentified with 6 degrees of freedom, and each of the parameters is individually identified or overidentified.

A major advantage of this specification over those reviewed above is that it allows the data to play a larger role in estimation. Apart from our assumption that variables at time 1 do not influence those at time 3, we do not fix any of the main parameters to prespecified values, but rather make the assumption that the coefficients, whatever they are, remain constant over time.⁴ In addition, the constrained models give us a good deal of flexibility in respecification. For instance, it is possible to relax the assumption of constant autoregressive effect ($a_1 = a_2$, $b_1 = b_2$ in Figure 1) and the assumption that time 1 rates have no direct effects on time 3 rates and still just identify the model as a whole. Finally, by introducing more waves of data, it is possible to relax some of the constraints, thus permitting a partial test of these assumptions. Since we had seven waves of data (for the years 1964–1970) available, we were able to take advantage of this flexibility in our analysis.

Data and Procedures

Data. Our analysis of the relationship between crime rates and clearance rates is

⁴ For a number of our specifications, we estimated models utilizing both unstandardized (metric) and standardized variables. The first set of models could not fit the data, while the latter set provided good fits. We are not completely certain of the reason for this, but suspect that it is a consequence of trends in the data. Over the years 1964–1970, reported crime rates rose steadily (e.g., total index offenses increased by 101%) while clearance rates experienced no comparable trend. Under this circumstance, a model that assumes constant metric coefficients would not be expected to provide a good fit; on the other hand, a model based on standardized variables avoids this difficulty by effectively detrending the data.

based on reported index offense rates and arrest clearance rates for 98 U.S. cities for the years 1964–1970. Two cities were dropped because of missing data from an original sample of 100 cities drawn by a proportional stratified random procedure from the total universe of cities with a population over 25,000 for which the F.B.I. had crime and arrest data. The 1970 edition of the F.B.I.'s *Uniform Crime Reports* indicates that the universe from which our sample was drawn represents over 90% of the urban population of the U.S.⁵

Data on population size, number of offenses known to police, and number of crimes cleared by arrest were supplied by the F.B.I. for each of the cities for each year from 1964 to 1970, for each of the seven index felonies. For each city, year and felony, *crime rate* was defined to be the number of offenses known to police for that year divided by the population estimate for that year; and *clearance rate* was defined as the ratio of offenses cleared by arrest to the number of offenses known to the police for that felony and that year.

Procedures. Although theoretical considerations suggest that lagged causal effects may exist, theory does not tell us precisely how long a lag to expect. Consequently we examined models with lags of one, two and three years. In models with one-year lags, correlations among the crime rates for consecutive years were so high that the correlation matrix could not be inverted. Under this circumstance, it is not possible to solve for the individual regression coefficients. Substantively, this means that too little change in the rates occurs over the period of a single year for us to detect accurately the impact

⁵ *Uniform Crime Reports* lists cities for which crime rate data are reported according to four strata by population size: 25,000–50,000; 50,000–100,000; 100,000–250,000; and over 250,000. Using the list of cities in the 1968 edition of *Uniform Crime Reports*, we randomly selected 53, 29, 11 and seven cities from each of these strata, respectively. Those numbers are proportional to the number of cities in each stratum of the *Uniform Crime Report's* list of cities. They were drawn to total 100, because that is the number of cities for which the F.B.I. indicated a willingness to supply arrest data.

of a predictor on this change. Thus, if there are lagged effects of any substantial magnitude, they must involve lags of more than one year. When a time lag of two years was employed, the correlations, though still high, were no longer too high to permit matrix inversion. Changes in rates over a two-year period were more substantial, and consequently more discernible. Models with three-year lags yielded results that were similar to those with two-year lags, and are not reported here.

With the exception of the crime rate and clearance rate at time 1, no exogenous variables are explicitly introduced into any of these models. In order to deal with the problem of misspecification and spuriousness, it would have been preferable to have had such controls, but thus far we have been unable to develop adequate data of this type. We note, however, that the problem of bias resulting from the omission of exogenous variables should be less serious in a panel model than in a cross-sectional analysis, as earlier values of C and A are controlled, and this will partly control for the effect of exogenous causes of C and A.⁶

A series of specifications, all generalizations of Figure 1, were estimated. The best fit was obtained by a four-wave model (1964, 1966, 1968, 1970) in which the standardized crime and clearance rates at time t were assumed to depend linearly on one another at times t and $t-1$,

⁶ The two-variable model will provide unbiased estimates in the face of exogenous causes of C and A when the exogenous variables have created a spatial distribution of crime rates and arrest rates but no longer influence those rates; and also when the effect of the exogenous variables persists provided that lagged cross effects vanish beyond a certain point and the exogenous variables remain constant in time. In the latter case, the panel model effectively controls for omitted exogenous variables even if it is not known what they are or exactly how they influence the dependent variables. Since most of the variables that are expected to influence crime rates and clearance rates (e.g., demographic, socioeconomic, political and cultural variables) do not change much from one year to the next, we believe the assumption of constancy should be fairly safe so long as the data are collected over a limited time span. For a complete discussion of issues related to the question of bias in this model, see Greenberg and Kessler (forthcoming).

and all autoregressive coefficients were treated as free parameters. Cross-coefficients linking time 4 with time 3 were constrained to equal those linking time 3 with time 2, but no constraints were imposed on the coefficients linking times 1 and 2. This procedure permits a partial test of the assumption that coefficients remain constant over time. The coefficients representing instantaneous influences were all constrained to remain constant; serial correlation among error terms was assumed to be absent, but correlations among contemporaneous error terms were estimated.⁷

Results. We used LISREL III (Jöreskog and Sörbom, 1975) to estimate all the models discussed below. This procedure provides maximum-likelihood estimates of regression coefficients in overidentified models and also has an option for imposing the constraints that characterize the models. The fit of a model to the observed data is evaluated by comparing the observed matrix of correlations among the crime and clearance rates with the matrix predicted by the model using the parameter estimates generated by the maximum-likelihood procedure. This evaluation was done both by inspection and by use of an appropriate chi-square goodness-of-fit test statistic with degrees of freedom equal to the number of overidentifying restrictions in the model.

We estimated eight applications of this model, one for each of the seven index offenses and one for total index crime. In only one instance (rape) was there a statistically significant difference between the observed and predicted correlation matrices at the 0.05 level (for the other categories, the probability of obtaining a discrepancy as large as the one observed ranged from $p > 0.50$ for total offenses to $p > 0.95$ for burglary), and here the sub-

⁷ Our estimates would be biased in the presence of serially correlated errors. To check that this was not a problem, we made use of the fact that our models can be identified in the presence of first order serially correlated errors using only time 1 variables as instruments. We found that the parameter estimates obtained for total offenses by this procedure differed only in the third decimal place from those obtained on the basis of the assumption that serial correlation of errors is absent.

Table 1. Parameter Estimates^a for Panel Model for F.B.I. Index Offenses^b (N=98)

Coefficient	Offense

^a X_iY_j denotes the standardized regression coefficient for the causal effect of variable X at time i on variable at time j. The 95% confidence limits for starred coefficients do not include zero.

^b See text for description of the model.

stantive discrepancy between the two matrices was quite small, with a mean absolute discrepancy between elements of only 0.02 and only two discrepancies larger in magnitude than 0.10. In light of this correspondence, we interpreted the parameters estimated by this model for all eight crime categories.

Table 1 presents the parameter estimates for the eight versions of this model, one for each index offense and one for total crime. The results are presented in three panels, corresponding to (1) the effects of arrest on crime, (2) the effects of crime on arrest, and (3) unanalyzed cross-sectional relationships.⁸ These are discussed in turn.

Panel 1 provides information about the impact of arrest rates on crime. Of the 24 coefficients, only two have 95% confidence limits that do not include zero. The only lagged coefficient that is significantly negative occurs for assault, but it is quite small in magnitude (-.113) and is not stable over time; the only instantaneous coefficient whose 95% confidence limits do not include zero is the coefficient for homicide, and it is *positive*, though only moderate in size (0.38).

⁸ As the estimates of stability parameters are of less interest they are not presented here, but will be furnished by the authors upon request.

The second panel provides evidence concerning the effect of crime on arrests. Coefficients for the instantaneous and lagged effect of crime on arrests are moderate to substantial for all offenses but rape. In the case of murder, burglary, larceny, and total offenses the instantaneous effects are negative, while for assault, robbery and auto theft they are positive. However, the standard errors for these coefficients are large (in general, standard errors for the clearance rates are larger than those for the crime rates), and none of the coefficients achieves statistical significance at the 0.05 level.

Finally, panel 3 shows the cross-sectional exogenous correlations among the crime and arrest rates at time 1 for each offense, and the cross-sectional correlations among the error terms for the offenses. Examining the former, we see that six of the eight correlations are statistically significant; those for murder and rape are positive, while those for burglary, larceny, auto theft and total offenses are negative. In a cross-sectional bivariate analysis these correlations would have been taken as evidence of the effect of arrests on crime, an interpretation which our results call into question.

^{*} The correlations among the residual error terms tell us how well our model has done in accounting for the cross-sectional

correlation over each of the subsequent time points of the panel. These correlations measure the influence of exogenous variables on both rates. If the correlated error terms were comparable to the exogenous cross-sectional correlations, it would indicate that the cross-sectional correlations are primarily due to unconsidered exogenous variables. This is only partly the case in our data. With the exception of assault, the correlated error terms are smaller than the exogenous correlations, though in some instances not entirely negligible. However, none of these correlations is statistically significant. Taking this finding, together with the absence of evidence for substantial cross-effects between crime rates and clearance rates, we see that much of the cross-sectional correlations are due to the internal stabilities of the rates themselves, and the initial correlations among these rates, which have not been analyzed. In our data, then, initial correlations brought about by historical forces that no longer operate, together with the natural changes in the rates themselves and the effects of omitted exogenous variables (e.g., socioeconomic and demographic variables), account for the major part of the cross-sectional correlations at later points in time. The reciprocal influences of crime on arrests and arrests on crime are negligible by comparison.

On the basis of these findings we estimated a model in which all autoregressive effects were estimated, but *all* cross effects were fixed at zero. The probability that the discrepancies found between observed and expected correlations could have arisen by chance was greater than 0.20 for homicide, assault and auto theft; greater than 0.30 for rape and robbery; greater than 0.50 for total offenses; greater than 0.70 for burglary; and greater than 0.80 for larceny. On the basis of this test and the tests for the individual parameters in Table 1, we conclude that none of the cross effects in our original model is significantly different from zero. Aggregate criminal activity for the F.B.I. index offenses is not substantially influenced by marginal variations in arrest clearance rates within the range found in our sample of American cities.

Discussion

Although our finding that arrest rates have no measurable effect on reported crime rates is contrary to the deterrence hypothesis, there are a number of ways to interpret our findings consistent with the deterrence doctrine. One possible explanation lies in the interdependency of criminal justice sanctions. Arrest is not a "pure" sanction; an individual who is arrested faces a stochastic distribution of dispositions ranging from dismissal of charges to conviction and imprisonment and, for some offenses, execution. If prosecutorial and judicial agencies respond with greater leniency to the caseload pressures generated by higher arrest rates, or if higher arrest rates are achieved by arresting suspects on the basis of weak evidence that will not stand up in court—with more dismissals as the consequence—the net effect could be to nullify any crime prevention effect due to arrests alone.

Another possible explanation for this seeming insensitivity of crime rates to changes in the clearance rate is that prospective offenders are for the most part ignorant about marginal changes in the probability of being arrested after involvement in an offense. Unless information about sanctions is communicated to potential offenders, variation in sanctions cannot be expected to deter (though it may influence crime rates in other ways, such as through incapacitation, if sanctions entail incarceration).

It is also conceivable that for some offenses, the consequences of an arrest for most of those arrested are not sufficiently serious to make an arrest an effective sanction; or that the stigmatizing effects of an arrest nullify any crime-prevention effects.

The cross-sectional correlations between clearance rates and crime rates in our data are comparable to those reported in the studies of crime rates that have appeared over the last decade (Tittle and Rowe, 1974; Logan, 1975; Brown, 1978). We therefore conclude that these studies, which have been interpreted as lending support to the deterrence doctrine, do not do so. Our analysis strongly suggests that the correlations interpreted in these studies as evidence of crime deterrence

may in fact have been spurious. Only through the use of statistical procedures that are capable of disentangling the various causal effects that are expected on theoretical grounds to link crime rates and punishment levels is it possible to draw inferences about the effect of punishment on crime. Previous studies of crime rates have failed to do this.⁹

⁹ This observation is applicable not only to research that has analyzed aggregated crime rates, but also to studies of the relationship between self-reported criminal activity and perceptions of risk, as perceived risk could be influenced by participation in illegal activity, as well as a cause of it.

THE USE OF PEARSON'S R WITH ORDINAL DATA*

ROBERT M. O'BRIEN

California State College

American Sociological Review 1979, Vol. 44 (October):851-857

Through the use of computer simulations, Labovitz's (1970) examination of the effects of "randomly stretching" measurement scales on the correlation between these stretched scales and an equal distance scoring system are reformulated and extended. Specifically, we examine the effects of the number of rank categories (C) for rank-order variables on the product moment correlation (r) between stretched scales and an equal distance scoring system. The stretched scales are drawn from three types of distributions: (1) the uniform distribution (i.e., the one used by Labovitz), (2) the normal distribution, and (3) a skewed distribution (log-normal distribution). We find that the average correlation (\bar{r}) between the equal distance scoring system and the stretched scale is quite high for both the uniform and normal distributions, and that \bar{r} increases with C only when C is greater than four or five. Thus, contrary to suggestions in the literature, \bar{r} is not a monotonic function of C . More importantly, for the skewed distribution, \bar{r} is a monotonically decreasing function of C and is substantially smaller than \bar{r} 's based on uniform and normal distributions. The implications of these findings for the use of Pearson's r with rank-order values are discussed.

There has been a great deal of controversy concerning the use of "interval-level statistics" with "ordinal-level data." In sociology much of this controversy has focused on the problem of multivariate analysis using ordinal variables. One approach to multivariate analysis of ordinal data is to argue that an ordinal statistic (Kendall's tau) calculated from ordinal-level data may be used as an analogue to Pearson's product moment correlation coefficient (r). The ordinal correlation coefficients are then employed in the standard formulas for multiple regression/correlation, partial correlation, and so on (Hawkes, 1971; Smith, 1974). Others have criticized the use of ordinal measures of association as analogues to Pearson's r (Wilson, 1974; Kim, 1975; 1978; Allan, 1976; Vigderhous, 1971). A second approach recommends the calculation of interval statistics directly from ordinal data, i.e., treating the ordinal data as if it were interval (Labovitz, 1967; 1968; 1970; 1971; 1972; 1975; Borgatta, 1968; Borgatta and Bohrnstedt, 1972). This approach has been criticized by Mayer (1970; 1971), Schweitzer and Schweitzer

(1971), Vargo (1971), Wilson (1971) and Henkel (1975).

The most influential proponent of the second approach has been Sanford Labovitz. Using simulation techniques (1967; 1970), he attempted to demonstrate that the use of interval-level statistics with ordinal-level data does not lead to large errors (at least for certain types of interval-level statistics). In his 1970 article, he demonstrated that "monotonic random scoring" (MRS) systems are highly correlated with equal distance scoring (EDS) systems.¹ Specifically, he transformed an ordinal scale with 36 rankings by assigning a random number from a uniform distribution to each category in the following manner:

- (1) the assigned numbers lie in the range of 1 to 10,000, (2) the assignment of numbers is consistent with the monotonic function of the ordinal rankings, (3) any ties in the ordinal rankings are assigned identical numbers, and (4) the selection of a number is made on the basis of a random generator in the computer program. (Labovitz, 1970:517)

* Direct all communications to: Robert M. O'Brien; Department of Sociology; California State College; San Bernardino, CA 92407.

I wish to express my appreciation to three anonymous *ASR* reviewers for their helpful comments on a previous draft. Thanks are also due to Jane Rowland, our department's master typist.

¹ The term *monotonic random scoring* (MRS) is used to indicate "randomly stretched" scales of the type utilized by Labovitz (1970:517). Equal distance scoring (EDS) refers to scoring systems in which the numbers assigned to rank-order categories are equally spaced, e.g., ranking ten occupations in terms of status and using the numbers 1, 2, 3, . . . , 10; or 2, 4, 6, . . . , 20.

Using this procedure, Labovitz randomly stretched 18 ordinal scales and correlated each of these scales with an equal distance scoring (EDS) system. These product moment correlations were quite high; in fact the lowest Pearsonian r between the EDS and a randomly stretched scale was .97, and the mean value of r was .99. Thus, if the underlying ("true") intervals between ordinal categories are not equal, but are instead "randomly different," this creates little distortion when using Pearson's r . Labovitz (1970:523) concluded that "certain interval statistics can be given their interval interpretations with caution (even if the variable is 'purely' ordinal), because the 'true' scoring system and the assigned scoring system, especially the equidistant system, are always close as measured by r ."

Several criticisms have been directed toward Labovitz's simulation. Of particular importance for our purposes are those of Mayer (1971) and Schweitzer and Schweitzer (1971) who argue that monotonic transformations which are *systematic*, instead of random, can lead to considerably lower values of r than those reported by Labovitz. They demonstrate that certain "rather extreme" monotonic transformations (e.g., exponential transformations) result in lower values of r . However, Kim (1975) has pointed out that even systematic monotonic transformations of a substantial nature (e.g., $X = X^2$) do not appreciably reduce the correlation between an equal distance scoring system (X) and its monotonic transformation (X^2).

Many sociologists find Labovitz's (1970) study persuasive. For these sociologists Labovitz's MRS represents "fairly" (if not more than fairly) the degree to which most ordinal scales differ from interval scales in the social sciences. However, Labovitz's simulations are limited in two very important ways. First, his simulations involved a rank-order variable with many categories (31 different categories). He did not examine the correlation between EDS and MRS when C (the number of rank categories) is small. Such an examination is necessary if Labovitz's arguments are to be extended

to the use of Pearson's r with rank-order variables which have few categories.²

Unfortunately the literature pertaining to this question is not very helpful. On the one hand, there is reason to believe that the correlation between EDS and MRS decreases as C increases. For instance, Schweitzer and Schweitzer (1971) demonstrate that for a number of *nonrandom systematic* monotonic transformations, the value of r decreases as C increases. Morris (1968) argues that as C increases the number of arbitrary assumptions concerning the distances between pairs of ranks and their corresponding MRS increases, and thus, r is an inverse function of C . On the other hand, Labovitz (1970) argues that as C increases the correlation between EDS and MRS increases. Kim (1975:288) provides a rationale for this position:

Since most phenomena we deal with vary within a limited range, as we examine more cases throughout the range the gaps between adjacent true values are likely to decrease. Therefore, as Labovitz noted, the errors in conversion will diminish as the number of cases increases, unless the ordinal distortion is systematic and extreme.

While the technical arguments concerning the relationship between the number of categories and the correlation between EDS and MRS continue, the social researcher is left with little practical guidance as to the use of Pearson's r with ordinal variables which have few categories.

A second limitation is that Labovitz's simulations involved the selection of random numbers from a single type of underlying distribution: a uniform distribution. This procedure is justified only if it is assumed that the underlying (interval level) distribution of the (ordinally measured) variable is uniform. The implicit assumption is that the ordinal values (EDS system) are assigned consistent with the

² Several authors have cited Labovitz (1970) to justify the use of ordinal variables as if they were on an interval level. For example: Roof (1974) uses Labovitz's paper to justify the treatment of a Guttman scale with seven categories as an interval variable; Ball (1972) uses Labovitz's paper to justify the use of an ordinal-level variable as interval with as few as four categories.

monotonic ordering of a random sample of scores from the underlying distribution. Thus, if occupational status is measured ordinally using 30 categories of occupations, Labovitz's procedure assumes that the 30 occupational categories are randomly drawn from an underlying occupational status dimension which has a uniform distribution. However, it might be more reasonable to assume that the underlying status dimension is normally distributed, with most occupations having a moderate degree of status and only a few having a high or low degree of status. Or perhaps it is even better to assume that most occupations have a moderately low status and only a few have high status (i.e., a positively skewed distribution). There is no literature which examines the effects of these assumptions on the value of the correlation between EDS and MRS.

This study addresses three major questions: (1) What is the effect of assuming that the underlying distribution is uniform, normal, or log-normal on the correlation between EDS and MRS? (2) What is the magnitude of the correlation between EDS and MRS when C is small? and (3) What is the relationship between the size of this correlation and C ; i.e., does Pearson's r increase, decrease, or behave in some other manner as C increases? The answers to these questions have practical implications for researchers using Pearson's r with rank-order data.

Procedures and Results

To answer these questions concerning the effects of the type of distribution and the number of rank categories on the magnitude of the correlations between EDS and MRS, a simulation technique was employed. For the monotonic random scores from the uniform distribution, this simulation followed the rules outlined by Labovitz (1970:517). Specifically, for each number of categories (C), C random numbers from one to 10,000 were generated and monotonically ordered from the lowest to highest value.³ These values were

then correlated with an equal distance scoring system consisting of the integer values one to C . For the monotonic random scores from the normal distribution and log-normal (positively skewed) distribution, the C scores were randomly generated, rounded to three decimal places, and then ordered monotonically from the lowest to highest value.⁴ These values were then correlated with an equal distance scoring system consisting of the integer values one to C . The number of independent correlations calculated to determine the average Pearsonian correlation (\bar{r}) in each distribution was 2,000 when the number of categories was nine or less and 1,000 when the number of categories was greater than nine.

Table 1 presents the results of these simulations for the uniform and normal distributions. For the MRS based upon the assumption that the underlying distribution is either uniform or normal, we note the following: First, when the number of categories is small the value of \bar{r} is quite high, e.g., when $C = 3$, $\bar{r} = .9518$ for scores from the uniform distribution, and $\bar{r} = .9552$ for scores from the normal distribution. Second, \bar{r} is not a monotonic function of the number of categories. For the uniform distribution, the value of \bar{r} is equal to 1.00 when $C = 2$; .9518 when $C = 3$; .9462 when $C = 4$; .9493 when $C = 5$; and from that point on increases as the number of categories increases. For scores from the normal distribution, the relationship between C and \bar{r} is similar. Thus, contrary to suggestions in the literature, the relationship between r and C is curvilinear rather than monotonic. Third, although the values of \bar{r} are rather similar for the uniform and normal distributions when C is small, the correlations based on scores from the normal distribution are somewhat smaller than those based on the uniform distribution when C is greater than six or seven. Although the differences between these correlations are

³ The intrinsic function, RANF, in an extended version of fortran (Control Data Corporation, 1978) was used to generate uniformly distributed random numbers.

⁴ The "direct method" recommended by Control Data Corporation's (1973:40-1) Math Science Library was used to generate the random scores from a standard normal distribution. To generate random scores from the log-normal distribution, we raised e ($= 2.7183$) to powers of the normally distributed random numbers.

Table 1. Results for the Scores from the Uniform and Normal Distributions

Number of Categories (C)	Uniform Distribution			Normal Distribution		
	Average \bar{r} (\bar{r})	S.D. of \bar{r}	S.E. of \bar{r}^\dagger	Average \bar{r} (\bar{r})	S.D. of \bar{r}	S.E. of \bar{r}^\dagger
2	1.0000 ^a	.0000 ^a	.0000 ^a	1.0000 ^a	.0000 ^a	.0000 ^a
3	.9518	.0417	.0009	.9552	.0400	.0009
4	.9462	.0417	.0009	.9492	.0407	.0009
5	.9493	.0375	.0008	.9495	.0386	.0009
6	.9523	.0341	.0008	.9512	.0378	.0008
7	.9575	.0300	.0007	.9562	.0345	.0008
8	.9594	.0283	.0006	.9583	.0332	.0007
9	.9643	.0243	.0005	.9602	.0315	.0007
12	.9695	.0205	.0006	.9612	.0260	.0008
15	.9762	.0163	.0005	.9633	.0250	.0008
18	.9795	.0145	.0005	.9636	.0254	.0008
27	.9856	.0088	.0003	.9704	.0184	.0006
36	.9886	.0078	.0002	.9708	.0170	.0005

^a No matter what monotonic transformation is made, the correlation is 1.00 when there are only two categories.

[†] When the number of categories is two through nine, 2,000 r 's were computed; when the number of categories is 12 or above, 1,000 r 's were computed.

small, the standard errors of \bar{r} are, in each case, less than .001.⁵ Fourth, the stability of \bar{r} is less when C is small. This can be seen by examining the estimates of the standard deviation of \bar{r} contained in Table 1. This is an important finding, since even if the mean value of \bar{r} is quite high when C is small, there is still a "good chance" of obtaining a relatively low value of \bar{r} .

For MRS based upon the assumption that the underlying distribution is log-normal, the results are dramatically different. Examining Table 2, we find that \bar{r} is a monotonically decreasing function of the number of categories; e.g., when $C = 3$, $\bar{r} = .9445$; when $C = 6$, $\bar{r} = .9016$; and when $C = 36$, $\bar{r} = .7905$. In addition, the values of \bar{r} are lower than those for the uniform and normal distributions at all levels of C (except when C equals two) and this difference increases as C increases. Furthermore, the standard deviations of the \bar{r} 's are typically much larger than those for scores based on the uniform and normal distributions.

Discussion

Labovitz's (1970) paper represents probably the most influential justification

for using Pearson's r with ordinal-level variables to have appeared in the sociological literature. In that paper he attempts to assess the amount of distortion in Pearson's r which results from treating rank-order values as if they were interval. Throughout his discussion it is assumed that the ordinally measured variable is based on an underlying variable with an unknown interval metric. His procedure is to assume (implicitly) that the distribution of the underlying variable is

Table 2. Results for Scores from a Log-Normal Distribution

Number of Categories (C)	Average \bar{r} (\bar{r})	S.D. of \bar{r}^\dagger	S.E. of \bar{r}^\dagger

^a No matter what monotonic transformation is made, the correlation is 1.00 when there are only two categories.

[†] When the number of categories is two through nine, 2,000 r 's were computed; when the number of categories is 12 or more, 1,000 r 's were computed.

⁵ This finding is consistent also with the asymptotic expectations presented in Stuart (1954). As the number of categories approaches infinity the expected correlation between EDS and MRS from a uniform distribution is 1.00; the correlation between EDS and MRS from a normal distribution is .9772.

uniform and that the ordinal scoring of the variable does not correspond to equal intervals of the underlying variable, but instead to intervals of a randomly different size. Two important limitations of his approach should be noted: (1) he assumes (implicitly) that the underlying variable has a uniform distribution, and (2) he deals only with the case in which there are 31 different categories of the ordinal variable. Thus, his results pertain specifically to the use of rank-order values as interval when the underlying distribution is uniform and the number of categories is relatively large.

In this investigation, we have found that if one is willing to assume that the underlying variable is either uniformly or normally distributed, the use of rank-order values causes little distortion in r . In fact, for those cases with the most severe distortion, i.e., where the number of categories is only four or five, the average Pearsonian r is approximately .95. However, even if the underlying distribution is uniform or normal the distortion in r may be greater than the .95 figure would indicate, since there is variation around the mean value of r and this variation is greatest when the number of categories is small. This can be seen by comparing the standard deviation for r in Table 1 when C is small and when C is large.

The situation is dramatically different if one assumes that the underlying distribution is quite skewed (log-normal).⁶ In this situation our results do not support the use of rank-order values as if they were interval. For example, when the number of categories is six, $r = .9016$ for the log-normal distribution compared with .9523 for the uniform and .9512 for the normal distribution; in addition, its standard deviation is almost twice as great as those for the uniform and normal distributions. The comparison is even more damaging

for this skewed distribution as the number of categories increases. Errors of this magnitude are likely to lead to much larger errors in multivariate analysis, e.g., using a correlation matrix as input for a regression analysis. Thus unless the researcher is willing to make an assumption about the form of the distribution underlying the ordinally measured variable, the results of our study and of Labovitz's (1970) study cannot be used to justify the use of Pearson's r with rank-order data. Note, however, that the researcher may have reasonable grounds for assuming that the distribution of the underlying variable is not highly skewed (e.g., Borgatta and Bohrnstedt, 1972).

The higher correlations between EDS and MRS from the uniform distribution are probably due to the fact that the scores from this distribution are not systematically distorted by equal distance scoring, but only randomly distorted. For the normal distribution, however, there is some systematic distortion since the scores in the underlying distribution are "bunched" toward the center of the distribution, while the equal distance scoring system treats all of these scores as equally spaced. In the log-normal distribution the differences in the sizes of the intervals between scores is greater than in the normal distribution (see fn. 6) and thus the assignment of rank-order values to these scores creates even greater distortion.

The approach taken in this study hopefully has resolved the debate concerning the relationship between the number of categories and the correlation between EDS and MRS, when the scores are drawn from a uniform distribution. Our results indicate that both Morris (1968) and Labovitz (1970) were partially correct. When the underlying distribution is uniform (or normal), \bar{r} first decreases as C increases and then increases. The value of \bar{r} reaches its nadir when C equals four or five and increases thereafter. Using a rationale somewhat similar to Morris's (1970), we suggest the following explanation of these results: For distributions such as these, where the systematic distortion resulting from the use of EDS is not too great, increasing the number of categories increases the possible distortion.

⁶ The log-normal distribution is somewhat more skewed than the distribution of income in the United States. For our simulation, values of various percentile points are reported below: 1st centile point = .10; 10th centile point = .28; 20th centile point = .43; 30th centile point = .59; 40th centile point = .78; 50th centile point = 1.00; 60th centile point = 1.29; 70th centile point = 1.69; 80th centile point = 2.32; 90th centile point = 3.60; 99th centile point = 10.24.

tion (see, e.g., Abelson and Tukey, 1963; and Morris, 1968), but at the same time decreases the likelihood of having extreme gaps between the underlying values. The first tendency predominates when C is small, but is "overwhelmed" as the number of categories is increased. When the underlying distribution is log-normal, however, the relationship between \bar{r} and C is negative (i.e., \bar{r} is a monotonically decreasing function of C). In this case, it may be suggested that the likelihood of having relatively extreme gaps between the underlying values does not decrease rapidly. In fact, when C is small there is a good chance that one of the extreme values in the positively skewed tail of the distribution will not be selected. This is not the case when C is large.⁷

Finally, it should be noted that the correlation between the EDS and the scores from the underlying distribution can be viewed as a type of validity coefficient, i.e., the correlation between the values or scores for the underlying construct and the equal distance scoring system measure of the construct. A correlation of .95 indicates that the underlying interval-level variable shares 90.25% of its variance in common with its equal distance scoring system representation. Clearly, however, this validity coefficient reflects only one possible source of invalidity in the measurement of the underlying construct. Specifically, it reflects the amount of invalidity introduced as a result of using EDS to represent values from a particular underlying distribution. The long run solution to this particular aspect of measurement invalidity is to move beyond simple rank-order measurement whenever possible.

COMMENTS

CRITIQUE OF A RECENT PROFESSIONAL "PUT-DOWN" OF THE HAWTHORNE RESEARCH

(COMMENT ON FRANKE AND KAUL, ASR
OCTOBER, 1978)*

The lead article by Richard Franke and James Kaul in the October 1978 issue of the *American Sociological Review* contains severe and unjustified criticism of the Hawthorne research, which was carried out at the Western Electric Company in Chicago in the late 1920s and reported in detail by Fritz Roethlisberger and William Dickson (1939) in their monumental *Management and the Worker*. According to Franke and Kaul (1978:624), Roethlisberger and Dickson concluded that the "measured experimental variables had little effect [on output], but that the unmeasured quality of human relations of workers to management and peer groups was responsible for most output improvements observed in the first four experiments." As most social scientists will recall, in addition to dependent variables measuring output, the "measured experimental variables" included as independent variables rest periods and hours worked per day and per week. Using raw statistical data from the original research plus some data not analyzed in *Management and the Worker*, Franke and Kaul (1978:627) undertake a complex statistical analysis of the "measured experimental variables." They add several dichotomous variables which

are expressed as dummy variables of zero to one for managerial discipline (the replacement of two of the five workers, with one of the replacements assuming the role of straw boss), and for the occurrence of the economic depression, the supply of defective raw materials for two periods, the temporary voluntary replacement of one worker, and for the change from a large group to a small group incentive system of pay after the first two experimental periods.

They claim that their analyses "differ starkly from most earlier descriptions of the findings of the Hawthorne experiments" (Franke and Kaul, 1978:635) because

there seems to be no substitute for quantitative analysis. . . . Quantitative analysis enables the scientist to separate fact from fiction. . . . To as-

sume that output changes resulted from unmeasured changes in the human relations of workers therefore seems injudicious, even though it was the assumption of the Hawthorne researchers and has been accepted and built upon by many social scientists over the past several decades. (Franke and Kaul, 1978:638)

To the contrary, Franke and Kaul (1978:638) report that "most of the variance in production rates during the first relay experiment could be explained by measured variables." Using stepwise regression they state that

differences in rates of hourly output by the first relay group are explained in model 1 through managerial discipline (79%), economic depression (an additional 14%), and through scheduled rest time (4%). Most of this 97% variance explanation appears to have resulted from the imposition of managerial discipline, which included better performing replacement workers as well as the disciplinary example, from the beginning of period 8. (Franke and Kaul, 1978:630-1)

Thus they find no support for Roethlisberger and Dickson's conclusions, but strong evidence that what they call "managerial discipline" and fear of job loss due to the onset of the depression explain 93% of the variance associated with increased output.

Although Franke and Kaul acknowledge that the Hawthorne studies were "seminal" and "led to widespread acceptance of human relations as a primary factor in worker performance," (Franke and Kaul, 1978:638), they find no support for the notion "that economic benefits result from humanitarian activity," or even that "increase of output was due to a changed relation with supervision" (Franke and Kaul, 1978:636), in agreement with Argyle (1953). If they are correct, social scientists and management theorists should reject the conclusions of the Hawthorne research, despite its revolutionary impact on industrial relations practices beginning a half century ago. Have Franke and Kaul given Roethlisberger and Dickson and their brethren their coup de grace?

The first thing to be noted is the well-known temptation among quantitative researchers to manipulate those variables that can be easily quantified and to ignore those that cannot. Franke and Kaul reject the major conclusions of the Hawthorne researchers concerning the effects on output of employee morale, worker solidarity, subtle social control processes, and employee attitudes and feelings. But that is where the main contributions from the Haw-

* Direct all communications to: Walter I. Wardwell; Department of Sociology; University of Connecticut; Storrs, CT 06268.

thorne research lie, not with the intentionally manipulated and easily quantified variables. It is precisely because the original researchers were flexible in their research design, freely admitted their mistakes, and radically revised their theories and assumptions when required that their analysis has proved so valuable. Starting first with physiological variables (fatigue and the need for food and rest), they then discovered a need to reinterpret the relay assembly test-room data from the perspective of psychology. They invoked such concepts as attitudes and sentiments as the main explanatory variables for the changes in output that were not explainable as effects of the independent variables (rest periods and hours worked) that they originally chose to manipulate. Later, after still further analysis of the experimental data and of more than 21,000 interviews with individual workers, they determined that psychological modes of analysis were not adequate and again reconceptualized their research, this time from a sociological perspective. As a result, they designed the bank-wiring observation room phase of the research, clearly not an experiment, since no variables were intentionally manipulated (except for establishment of a neutral observation setting). The observation provided the researchers with their most important insights into the dynamics of the functioning of work groups and led to the most significant conclusions to be drawn from the entire Hawthorne research program. It is particularly significant that Franke and Kaul totally ignore this important phase of the research, admittedly difficult to quantify, in favor of the "measured variables," as they term them, from the earlier relay assembly test-group phase.

Of all the variables that Franke and Kaul analyze, the two most important turn out to be dichotomous variables that the Hawthorne researchers had not intended to be independent variables, though they were well aware of their impact on the research. These variables are the replacement of two operators after the seventh experimental period and the onset of the depression. The label *managerial discipline*, which Franke and Kaul use to describe replacement of the two operators, reveals their biased interpretation of the event. They state with no apparent basis in fact that the two operators were replaced "because of unsatisfactory attitudes in response to requests for greater diligence and more output" (Franke and Kaul, 1978:627). Actually they make three different misinterpretations of the event: as punishment for the two workers who were removed, as an implied threat to the remaining three workers, and as a reflection of the conscious intent of the researchers to infiltrate into

the group a worker who would become a "straw boss."

What actually did happen? It is certain that operators 1A and 2A had become so uncooperative with the research that Roethlisberger and Dickson used the words "hostile" and "openly defiant" to describe them. But it is important to keep in mind that the leader of the pair was discovered four months later, upon review of her medical records, to have had an anemic condition that could have been the root cause of her disaffection (Roethlisberger and Dickson, 1939:169-70) and that the request by two of the other workers "that either they or operators 1A and 2A be removed from the test room" (Roethlisberger and Dickson, 1939:55) was what impelled the researchers to action after a two-month effort to cope with the problem by less drastic means. Returning the workers to the main department was not viewed as punishment, nor was it so interpreted by the remaining workers, despite Franke and Kaul's speculation "that improvement resulted from the positive example of the two new workers, as well as from the aversive effects of management's disposal of two of the original workers" (Franke and Kaul, 1978:636). If the change had been intended or viewed as a threat, then output should have immediately increased as the result of "managerial discipline." But that did not happen. The record shows that the hourly output rates of operators 3 and 4, which had been rising rapidly during period 7, immediately ceased to rise and leveled off in period 8, the period following the switch of workers. Although operators 1 and 2 immediately began producing more relays than the two workers they replaced, their level of output did not exceed that of operators 3 and 4, as it should have done if they were role models. What is more, during periods 8 through 12 the hourly rates for all operators declined rather than increased, further evidence that the single episode of "managerial discipline," on which Franke and Kaul place their primary emphasis, could not possibly be the principal explanatory variable for the overall increase in output. The implication that operator 2 became the highest producer of the five and sometimes urged the others to produce more because management placed her in the room as a "straw boss" represents a gross distortion of the available evidence. In fact, she was selected from among the workers in the main department mainly to give her a change of job because she was grieving over the recent deaths of her mother and sister (Roethlisberger and Dickson, 1939:61-2). It is also relevant that her spurt of productivity did not occur until period 13; and in that spurt she was paced by her new friend,

operator 4, one of the original workers in the room.

An equally serious problem arises from the fact that managerial discipline is a dichotomous variable separating the first seven experimental periods from those that followed, while many other changes occurred gradually over the five-year span of the research, including subtle and complex qualitative changes difficult to quantify. Increases in group solidarity, in favorable attitudes toward the research and its goals, and in the workers' obvious pleasure in working under solicitous supervisors (which were among the most important but unintended effects of the original research design) must have developed gradually over the long life of the relay assembly test-room research. In addition, some of the most important changes occurred *within* experimental periods (e.g., in period 13, during which operators 2 and 4 exhibited large increases in hourly output). Such within-period changes are totally obscured by a statistical technique based on mean outputs for each period.

Franke and Kaul state that a second dichotomous variable, which they call the "onslaught of the great depression," accounts for 14% of the variance in average hourly output. They pinpoint its occurrence as "early in period 15," which extended from September 2, 1929 through April 5, 1930. However, the data which Roethlisberger and Dickson present and analyze in *Management and the Worker* extended only through June 29, 1929, marking the termination of period 13. How could "the onslaught of the great depression," which did not occur until the following September, explain variations in output rates going back to 1927? Actually, the impact of the depression on most American workers did not occur much before the stock market crash in October 1929. In the case of the relay assembly group, the impact could have come still later, since it was not until April 1930 that they were cut below 40 hours of work per week. By limiting their analysis in *Management and the Worker* to the first 13 experimental periods, ending June 29, 1929, Roethlisberger and Dickson were able to minimize the effects of the depression on the variables they studied.

In still other ways Franke and Kaul misrepresent the original Hawthorne analyses. They imply that Roethlisberger and Dickson deny the importance of the wage incentive, which was based on the small group of five workers rather than on a large group comprising the entire department. However, a more careful reading of *Management and the Worker* would have informed them that it was precisely in order to measure the independent effect of the small-group wage incentive that the second

relay assembly test group was set up. And it was in order to test the effect of all other variables (controlled and uncontrollable) except the small-group wage incentive that the mica splitting test group was set up. Franke and Kaul apparently fail to comprehend this because they state that the 15.5% improvement in hourly production rate in the mica splitting group "apparently result[ed] from the reduction of fatigue by use of rest pauses and fewer working hours" (Franke and Kaul, 1978:628, fn. 9), thereby ignoring the possible influence of other relevant variables (e.g., the fact of being studied, being placed in a segregated location, etc.). When only the effects of selected independent variables are examined to the exclusion of others, neither the confounding nor the genuine effects of the other variables can be determined.

Finally, Franke and Kaul seem to have only what Elton Mayo (1945), following William James, called "knowledge about" the complex and detailed research they criticized, not really "knowledge of" it. Their understanding of Roethlisberger and Dickson's analysis appears superficial, as though derived from secondary sources and others' interpretations, rather than based on in-depth familiarity with the rich material and analyses from the Hawthorne research. Certainly closer attention to *Management and the Worker* could have prevented their misinterpretation regarding "managerial discipline," discussed above. The most extreme statement of their position follows: "It is not 'release from oppressive supervision,' as suggested by Landsberger (1958), but its reassertion that explains higher rates of production" (Franke and Kaul, 1978:636). This statement also reveals an even more surprising bias on the part of the writers, only hinted at in their preference for "close managerial control" (Franke and Kaul, 1978:638) and their dislike of "humanitarian activity" (Franke and Kaul, 1978:636). Such sentiments are also expressed in the following citation, which fleshes out their favorable reference to the "conceptually simpler mechanisms such as those of scientific management (Taylor, 1911)":

These include the possible benefits of fatigue reduction, use of economic incentives, the exercise of discipline, and other aspects of managerial control. But it is precisely such factors to which we are directed by empirical analyses of the Hawthorne data. In particular, the discharge and replacement of two somewhat insubordinate workers were followed by higher individual and group production rates in the first relay experiment. Fairly strong evidence has been provided in recent years showing that proclivity to exert close managerial control can benefit the economic performance of individual managers (Miner, 1965), or organizations (Kock, 1965), and of whole societies

(Franke, 1973; 1974; 1977). (Franke and Kaul, 1978:638)

In contrast to most previous criticism of the Hawthorne research, which has tended to come from the ideological left because of presumed managerial bias in the concern with productivity, Franke and Kaul's critique, condemning the Hawthorne research for its concern with human relations and humanitarian activity in the workplace, and calling for a return to stronger emphasis on "discipline and other aspects of managerial control" (Franke and Kaul, 1978:638) appears to derive more from the ideological "right." It is indeed fascinating to discover that both sources of criticism of the Hawthorne research focus on variables such as hours worked, economic incentives, fear of unemployment, power to discipline, etc., and agree that human relations at work should be de-emphasized. However, the lessons of the Hawthorne researchers will probably continue to survive such attacks.

THE HAWTHORNE EXPERIMENTS: RE-VIEW*

Critical review is important for the improvement and application of science, and it is useful to participate with Walter I. Wardwell in this process. As noted in his critique (Wardwell, 1975), our analysis of the first relay experiment at the Hawthorne plant does explain most of the variance in production rates for the group of workers, as it also does separately for each individual (Franke and Kaul, 1978). In describing our study,¹ Wardwell expresses concern (1) over the meanings of the independent variables in the experiment, (2) over the use of quantitative data and procedures for unraveling complex social phenomena, and (3) over our interpretations of the results of this first truly quantitative analysis of the Hawthorne experiments.

Certainly it is advisable to be circumspect when reinterpreting a body of work historically as influential as the Hawthorne experiments of 1924-33, carried out by managers and employees of the Western Electric Company with help by consulting engineers and physical and social scientists at MIT and (later) at Harvard.² But

* Address communications to: Richard H. Franke; Department of Management; Worcester Polytechnic Institute; Worcester, MA 01609.

I am grateful to Charles Wrege for information about those who did the Hawthorne experiments, to Arthur Gerstenfeld for help in carrying the Hawthorne logs to Boston, and to Elke Franke for radical editing.

¹ His description is generally accurate, though not comprehensive, and on occasion it seems to reverse the order of evidence and conclusion in the Hawthorne study. In following the critique, the reader may wish to reexamine the Franke and Kaul article of October 1978. There are several misprints in that article: in the reference list, the book by Homans and the article by Rotinson were published in 1950 rather than 1959. A final misprint is in Table 3, where there are operators 2A + 2, not 2A + 2A, with no superscript.

² We perpetuated an error in suggesting that social scientists from Harvard were involved in interpreting the illumination experiments and in planning the first

certainly also, modern statistics and computers are tools that can help shed new light on previous assumptions. In addition, through use of many of the original documents³ which had

relay experiment (Franke and Kaul, 1978:624). In fact, Elton Mayo first visited the Hawthorne plant over April 24 to 26, 1928 (cf. Baritz, 1960:90; Whitehead, 1938, I:124; Wrege, 1979b), and "had nothing to do with the design of or conduct of the original illumination experiments [1924-27] or of the Relay Assembly Test Room [1927-33]" (Roethlisberger, 1977:48). As described by Wrege (1976; 1979a), those who were particularly important in determining the early illumination experiments were Clarence G. Stoll and George A. Pennock, Western Electric managers, and Dugald C. Jackson, MIT electrical engineering professor and chairman of the Committee on Industrial Lighting—an industry-supported research group associated with the National Research Council of the National Academy of Sciences (see also Snow, 1927, and Wiljanen, 1979). The illumination experiments were carried out and reoriented in part toward human relations by Western Electric managers, by Charles E. Snow, the field engineer for the Committee on Industrial Lighting, and by Homer Hibarger, who was Snow's assistant and a supervisor, observer, or experimenter in illumination, first relay, and second relay experiments, until laid off on April 29, 1932. In the first relay experiment, Hibarger and the Western Electric management (especially Pennock) appear to have provided most initiation and direction, often expanding upon observations and mini-experiments of Snow and Hibarger in the earlier illumination experiments. The involvement of Clair E. Turner, another MIT professor, began on April 16, 1928, and seems to have been substantial (cf. Roethlisberger, 1977:48; Turner, 1933; Wrege, 1979b). Finally, the Harvard researchers did have some contact with the first relay experiment beginning with Mayo's visit in 1928, and went on to participate in the nonreactive "experiments" and to provide the most influential descriptions of all of the events at Hawthorne—those written by Mayo, Whitehead, Roethlisberger and Dickson, and Homans, apparently using the documents noted here in fn. 3.

³ The 17 boxes of documents that we used at the Hawthorne plant in 1976 and 1977 now have been transferred to the archives of the Baker Library at Harvard University, and our complete microfilm record of these has been deposited at the Hawthorne plant and in the libraries of the University of Wisconsin, Milwaukee, Worcester Polytechnic Institute, and Harvard University. (A guide to these records is provided in the AAAS version of the ASR article by Franke and Kaul, 1978.) In addition, nine 11 × 18 inch log books from the Hawthorne experiments were obtained from the Hawthorne plant in January 1979 and have been deposited with the Harvard archives. These consist of: four volumes of daily and weekly logs from the first relay experiment, but only for the 24th experimental period (which is seen to have extended from March 1, 1932, until May 4, 1933, in somewhat altered form, rather than halting on February 8, 1933, as reported by Franke and Kaul, 1978:fn. 6); one volume of day-by-day sum-

been employed by Mayo (1933), Whitehead (1938), and Roethlisberger and Dickson (1939) to obtain their graphical representations and qualitative interpretations, but which have not been readily accessible to most subsequent researchers, a more accurate assessment of "what really happened at Hawthorne" should be possible. Thus the fact that our results and interpretations differ from those of many predecessors need not reflect upon the skills of the researchers involved. Indeed, under these conditions it would be surprising if the historical interpretations would not require change. This paper will elaborate some possible changes, as developed by Franke and Kaul (1978), in response to Wardwell's comments.

INDEPENDENT VARIABLES

Managerial Discipline

Wardwell objects to viewing the replacement of two of the five workers in the first relay experiment as "managerial discipline," i.e., punishment, threat, and provision (perhaps inadvertently) of a straw boss in the person of new operator 2. Undoubtedly there was greater output by operator 2 than by any other worker in each of the remaining periods 8 to 23, and there was a general productivity spurt following the replacement intervention, as shown by the data of Appendices 1 and 2 and the analyses of Tables 2, 3, and 4 (Franke and Kaul, 1978).

The intrinsic meaning of the managerial intervention at the beginning of period 8 is more difficult to ascertain. But the available records show that in period 6 both operators who were replaced had preferred the experiment over regular work:

Operator 1A: "I don't intend to go back in the other department."

Operator 2A: "I wish this test would last two more years."⁴

maries of the mica splitting experiment; and four volumes of daily and weekly logs from the bank wiring experiment. (A microfilm record of these volumes is to be made available by Harvard.) No original log books for the illumination experiments or for periods 1 to 23 of the first relay experiment yet have been seen by the present researcher, although these are known to have existed (cf. Whitehead, 1938, I:28; Wrege, 1976; 1979a; 1979b). Some additional records have been recovered by Wrege through investigations over several decades, and these were deposited with the Industrial and Labor Relations library of Cornell University in June 1979.

⁴ Progress Report No. 1, December 3, 1927, Section No. 9, page 8 (microfilm reel 1, listed as box 1, folder 3). These original operators number 1 and 2

Also, log notes as early as period 3 relate threats by the shop foreman that if excessive "talking and fooling" continued, "the girls . . . would be taken back to the regular department, and in the most offending cases laid off (dismissed from the company) if improvement was not made." This foreman "continued to exercise his functions as the disciplinary head of the Test Room" well into 1928, and to a lesser extent to the end of the experiment.⁵ Other pressures to improve efficiency included threats in period 7 by executives to remove privileges (Whitehead, 1938, I:116).

The role of new operator 2 as straw boss is described throughout chapters 16 and 17 of Whitehead (1938, I): "Op. 2 was the ablest member of the group, whether judged by intelligence tests or by any other standard" (120). "On the whole, Op. 2 succeeded in inducing a greater work interest amongst the other operators, but at times the latter showed some resentment" (123).

Op. 2 forced the group into a partial adoption of her enthusiasms; she constituted herself the keeper of its conscience; she admonished this one, encouraged that one, and built up an entire system of control based on social favors and prestige. (158)

Thus "managerial discipline" appears as a continuing factor rather than as a "single episode" as suggested by Wardwell, but the punishment administered in period 8 was needed to make it real. While it can never be completely clear what transpired in the minds of Western Electric managers and employees, either leading to or following the removal of operators 1A and 2A on January 25, 1928, "for a lack of co-operation, which would have otherwise necessitated greatly increased disciplinary measures" (Whitehead, 1938, I:118), the death of operator 2's sister in December 1927⁶ and the discovery in April 1928 by Mayo that operator 2A was anemic seem irrelevant to the intervention. The employees who were removed did value being in the experiment, so that removal can be seen as punishment; management did threaten punishment of various sorts; and the new operator 2 did function as a straw boss. Therefore, to label the intervention as an exercise of managerial discipline that well may have involved these elements is supportable.

later were relabeled*1A and 2A, as they are designated here and in the 1978 article.

⁵ Whitehead, 1938, I:112, in part from log for August 4, 1927.

⁶ Operator 2's mother died on March 5, 1928, so this could not play a role in her selection for the experiment.

The Depression

A second major variable in Franke and Kaul's report is the occurrence of the great depression, described by Galbraith (1954:103) as beginning October 24, 1929—i.e., occurring during the time of experimental period 15 (September 2, 1929, to April 5, 1930). Wardwell's imputation that we claim effects of the depression upon "productivity increases beginning in 1927" is simply wrong, since it was used as a categorical variable arising with the beginning of the depression, which occurred 26% of the way through period 15. While the meaning of the depression to Western Electric managers and workers is open to some speculation, there were test room discussions of lay-offs by April 1930 and an economically-determined reduction in working hours to 40 hours per week beginning on May 5, 1930, with a "loss of security . . . quite evident in the records from now on" (Whitehead, 1938, I:148-9). "The last two years [sic] of the log [August 1930 to August 1932] are filled with preoccupations with respect to reduced weekly hours and 'lay offs'" (Whitehead, 1938, I:164). Careful reading of the Hawthorne records thus supports the validity of an independent variable representing the depression, inclusion of which then allows consideration of output rates during periods 15 through 23 (cf. Franke and Kaul, 1978:fn. 6).

Of course, any effect of the depression upon prior output rates is inconceivable, but perhaps hardly more so than is a justification for the abrupt halt in Roethlisberger and Dickson's (1939) treatment of the first relay experiment with period 13, ignoring the last 3 years and 10 months—11 experimental periods—of the experiment. There was even one further experimental period fully before the depression (period 14, over July and August 1929), which showed a reduced rate of output and was not considered in *Management and the Worker*. (However, at least some of the remaining eleven experimental periods were considered in the earlier work of Pennock, 1930; Mayo, 1933; and Whitehead, 1938.) Unexplained neglect of available experimental data is dubious at best, and different or additional results are often obtained through more complete or systematic inclusion (see examples in different settings by Barrett and Franke, 1970; Clark, 1961; and Franke et al., 1977).

In summary, careful perusal of recorded attitudes, behavior, and circumstances indicate the influence of "managerial discipline" and of the depression upon the first relay experiment, and both should be considered in any quantitative or qualitative appraisal of it. Nevertheless, the arguments above, supportive as they are of

Franke and Kaul's (1978) interpretations, are based largely upon a selection of anecdotal comments. A critical reader of the records of the Hawthorne experiments well may discover additional comments that lead to alternate interpretations. Quantitative analysis seems a useful supplement to such evidence, and is treated below.

QUANTITATIVE ANALYSIS

Wardwell expresses concern over our focus upon tangible variables, to the exclusion of residual and qualitative explanations. It seems indeed that the major conclusions of the early Hawthorne researchers (and of most of those who followed) were that tangible independent variables such as rest periods, working hours, and pay incentives, had little effect upon output rates, and therefore that qualitative, intangible explanations were in order. Yet through the quantitative evaluation of these factors and the extension of test variables to include inadvertent but major and quite tangible occurrences in the experiment (which are authoritatively recorded by the experimenters as well as by some of the Harvard reporters of the experiment), it is possible to explain most of the variance in output quantity and quality for the group and for the individuals in the first relay experiment. It seems simply inappropriate to "explain" the output changes in the first relay experiment in terms of the intangible human relations effects noted as an "enlightenment" by Roethlisberger (1941:15-6), since little residual remains after applying a few quantitative variables of the experiment to the quantitative output evidence. If this is to be criticized, then at least a better argument should be made in particulars for any alternative way of thinking about the productivity changes.

In anyone's research, it is necessary to begin somewhere. Our work has begun with the major Hawthorne experiment, that in the first relay assembly test room. As Wardwell correctly states, there were other important studies at Hawthorne (cf. Franke and Kaul, 1978:Figures 1 and 2). But these, too, can be looked at more closely now. The second relay and mica splitting experiments are amenable to similar time-series analysis, as illustrated crudely in fn. 9 of the 1978 report. An exploratory study at the Worcester Polytechnic Institute already has yielded some results in explanation of output changes in the little-described illumination experiments; it shows statistically significant benefits of illumination as well as a "social hysteresis" effect of lesser response to reduction of positive factors in

production (cf. Wiljanen, 1979). Finally, investigation is just beginning of the long (ten months) 24th period of the first relay experiment. Since both the interviewing and the bank wiring experiment (which Wardwell suggests "led to the most significant conclusions to be drawn" from the entire Hawthorne research program") were nonreactive survey and observation, systematic quantitative interpretation could be more difficult, and Wardwell may be correct in suggesting that much will remain to "insight." Still, the daily and weekly data recently obtained for the bank wiring experiment (cf. fn. 3) may allow even in this case systematic analysis using a time-series approach such as that of Franke and Kaul (1978).

For the present case, the usefulness of quantitative analysis is well illustrated in refuting Wardwell's (1979) comment that: "If the change [replacing two of the five operators by two others] had been intended or viewed as a threat, then output should have immediately increased as the result of 'managerial discipline.' But that did not happen." But in fact it did. The results presented in Tables 2, 3, and 4 of Franke and Kaul (1978) do indicate an abrupt increase in productivity. The immediate effect of managerial discipline is shown even more clearly by a plot of the period-by-period output rates over time, as presented now in Figure 1. This graph of data from the earlier Appendix 1 shows an immediate and strong effect of the variable upon group output. Like

Note: X_1 , X_9 , X_{11} , and X_{13} are the symbols used in the regression analyses. The minutes of rest time per day (X_9) are shown for each period on the above plot (from 0 to 30 minutes). The dotted lines approximate the model 1 results for the group (cf. Franke and Kaul, 1978:Table 2).

Figure 1. Worker Productivity in Periods 1 to 23 of the First Relay Experiment at Hawthorne

effects of managerial discipline can be shown for each individual by plots of the individual output data from the earlier Appendix 2. Similarly, Wardwell's (1979) statement that "during periods 8 through 12 the hourly rates for all operators declined rather than increased" is incorrect, or at least misleading, as shown in the present Figure 1: group output rose twice and declined twice, with the larger of the declines (from period 11 to period 12) attributable to the elimination of rest periods.

Figure 1 reports mean output rates for each of 23 experimental periods, as represented by 23 dots connected with solid lines. Substantial within-period changes did occur (as also discussed by Parsons, 1974; 1978; with reference to a theory of gradual, feedback-induced output increase). However, net changes in productivity within periods were downward for nearly as many periods as they were upward (cf. Mayo, 1933:Plate VIII), so that the continued gradual increase in output rates sometimes attributed to the experiment is again not substantiated. Nevertheless, Wardwell's (1979) objection that "within-period changes are totally obscured by a statistical technique based on mean outputs for each period" is correct, and detailed day-by-day and week-by-week analyses should be undertaken.

In Figure 1 for the first seven periods, group hourly output responds positively to changes in minutes per day of scheduled rest time, except that output does not seem to rise much with more than 25 minutes of rest per day. Thus 25 minutes of rest were taken for the remaining experiment, except for period 12 (no rest). There is then an immediate response to "managerial discipline" (the replacement of two workers) at the beginning of period 8. A step level of higher production is maintained (with oscillation) from period 8 through period 14, until the depression early in period 15, when there begins a rise to a still higher and steadier level of output from period 16 to 23. The full-fledged effect of the depression seems to be delayed until period 16, when the operators heard of lay-offs, reinforced in period 17 by the operators' experience of a depression-related "loss of security." The positive response of the workers to economic adversity remains through period 23, with a slight unexplained rise in periods 22 and 23.⁷

These effects of rest, discipline, and depression are the same as model 1 of Franke and Kaul (1978), represented approximately by the dotted line in the present Figure 1. Whether we use the regression or the graphic method, the continuous effect of rest pauses and the

stepped effects of managerial discipline and the depression clearly are demonstrated. It is difficult to imagine that this demonstration, which is as strenuously objective as possible, arrived at through statistical analyses of historical productivity data, could lead Wardwell to conclude that Franke and Kaul's criticism of previous conclusions drawn from the Hawthorne experiments derives "from the ideological 'right.'"⁸ Recognition of the strong productivity effects of close managerial control and of economic adversity need not be equated with a "preference for" such conditions in the workplace, or even with an exclusive concern for productivity. Similarly, a study indicating the effectiveness of, say, bureaucracy, socialized medicine, or terror need not make the author a proponent of the phenomenon. Though the impact of the Hawthorne experiments can and will not be denied, to perpetuate findings no longer convincing hardly furthers the cause Wardwell seems to have at heart. Industrial democracy, participation, and quality of working life need not be sacrificed as goals in themselves, even if they are largely unrelated to subsequent productivity.

CONCLUSION

Wardwell agrees that the Hawthorne experiments have provided a foundation for much work in social science. But he does not find that our interpretations of those experiments, which differ from most of our predecessors, provide grounds for altered perspective. If our analyses were demonstrably incorrect or if there were more recent, substantial work confirming the earlier interpretations, Wardwell's objections certainly should not be brushed aside. In fact, however, he provides scant evidence that there are any major errors in the Franke and Kaul interpretations, and as indicated in the article there is much work elsewhere supporting our results.⁹

⁸ As noted by Franke and Kaul (1978:637), non-substantive criticism focused on ideology of the researchers has long plagued the Hawthorne studies. For example, Roethlisberger (1960:viii)

saw in the 1950s (the era of the cold war and the agonizing re-appraisals of intellectuals) a mounting concern with Mayo's ideological and personal beliefs. Was he for or against trade unions? Was he a fascist or a Communist? Was he preaching the gospel of Saint Luke or "Saint" Freud? Was he the arch priest of conservatism, the tool of business, and the exponent of the *status quo*? . . .

⁹ From the time at least of Fleishman et al. (1955) and Brayfield and Crockett (1955), and in later work through Vrcom (1964), Campbell and Dunnette (1968), Stogdill (1974), Locke (1976), and Locke and

⁷ All five operators were laid off in July and August of 1932, during the final period 24.

A clearer view of the Hawthorne studies and of the body of knowledge which has grown up partly dependent upon them may encourage us to do away with wishful thinking about social phenomena, and to realize that different aspects of industrial society do not necessarily exist in simple cause and effect relationships. Beyond the present, nonexistent humanitarianism-productivity relationship, one could point to the esteemed but equally fallacious assumptions that democracy causes industrial effectiveness (cf. Blau, 1956:80-3, 114-8; Dahrendorf, 1969:54; Franke, 1973), that an infusion of technology and capital investment is responsible for industrial development (cf. Clark, 1961; Franke, 1979), or that better nutrition leads to economic growth (Franke and Barrett, 1975). In all these cases, the testing of well-accepted theory using quantitative analysis can provide new insight into what really happens. If, as may result from the Hawthorne experiments, humanitarian objectives are pursued primarily for economic reasons, then the lack of an actual relationship is likely to frustrate either goal.

Since it is possible today to review the work of many of the pioneers of the social sciences and to reanalyze and replicate their evidence using recently developed techniques, new and sometimes contradictory results should be expected.

ON GINI'S MEAN DIFFERENCE AND GINI'S INDEX OF CONCENTRATION

(COMMENT ON ALLISON, ASR
DECEMBER, 1978)

Allison's (1978) treatment of the Gini's Mean Difference and the Gini Index of Concentration contains some errors. Below I provide correct definitional formulas as well as some computationally simpler equivalent expressions for both the Gini's Mean Difference (GMD) and the Gini Index of Concentration (GIC), and I correct other errors that resulted from use of inaccurate formulas.

1. The Definitional Formulas

Allison (1978:867) states correctly that the Gini's Mean Difference is "the average absolute difference between all pairs of individuals" and that the Gini Index of Concentration is the Gini's Mean Difference divided by twice the arithmetic mean. But his formula (3) is incorrect. The correct formula for the Gini's Mean Difference is

$$GMD = \frac{\sum_{i < j}^N \sum_{j=1}^N |x_i - x_j|}{N(N-1)/2} \quad (a)$$

(see, for example, Johnson and Kotz, 1970:67). In this formula, the numerator is the summation of all the pairwise absolute differences, and the denominator is the number of pairs (i.e., the number of combinations of N things taken two at a time). Notice that although Allison correctly described the GMD, he used the wrong denominator; that is, he used N^2 instead of using the number of pairs in a population of size N, namely, $(N(N-1)/2)$, as in formula (a) or instead of using twice the number of pairs, namely, $(N(N-1))$, as in formula (c) below.

The correct definitional formula for the Gini Index is

$$GIC = \frac{\sum_{i < j}^N \sum_{j=1}^N |x_i - x_j|}{N(N-1)/2} \bigg/ 2\mu. \quad (b)$$

Since the Gini's Mean Difference is the arithmetic mean of all the pairwise absolute differences, it may be regarded as the expected value of the difference between two random individuals. As Atkinson (1975:45) puts it,

Suppose we choose two people at random from the income distribution, and express the difference between their incomes as a proportion of the average income, then this difference turns out to be on average twice the Gini coefficient: a coefficient of 0.4 means that the expected difference between two people chosen at random is 80 percent of the average income.

2. Alternative Computational Formulas

It is useful to examine several equivalent expressions for any given definitional formula not only because one among them may be incomparably easier to calculate (and hence become the preferred "shortcut" method) but also because these restatements, often revealing the "inner workings" of the formula, lay bare the underlying relations between its constituent parts.

Allison (1978:867) offers an alternative expression in formula (4), but (4) is incorrect. There are many computationally equivalent formulas for the Gini's Mean Difference and the Gini Index of Concentration, and we now look at a few such equivalent expressions.

a. *The double summation formula.* The formula most often encountered in the statistical literature is

$$\text{GMD} = \frac{\sum_{i \neq j}^N \sum_{j=1}^N |x_i - x_j|}{N(N-1)} \quad (c)$$

(see, for example, Kellerer, 1968:239; and van der Vaart, 1968:294,297). In this formula, the notation on the double summation directs the user to sum, for each of the x_i , the absolute difference between it and each one of the remaining $N-1$ scores, thereby counting each pairwise absolute difference twice; the denominator then is adjusted to twice the number of pairs or $N(N-1)$. This formula seems to me to have little to offer by way of either enlightenment or ease of calculation.

b. *The symmetric pairs formula.* Johnson and Kotz (1970:67) provide an equivalent expression that does both illuminate the behavior of the Gini's Mean Difference and lighten the calculation task:

$$\text{GMD} = \frac{4}{N(N-1)} \sum_{j=1}^{N/2} \left[\frac{1}{2} (N+1-j) \cdot (X_{N-j+1} - X_j) \right] \quad (d)$$

where the X_j are the order statistics (arranged in ascending order of magnitude) and the j are the rank-order statistics. By defining the order statistics such as $x_1 \leq x_2 \leq \dots \leq x_N$, this formula can handle continuous as well as discrete data (see Johnson and Kotz, 1969:27; Johnson and Kotz, 1970:2; Greenberg, 1968:183; and Allison, 1978:866). The rank-order statistics are the set of positive integers from 1 to the population size N (see David, 1968:196-7).

This formula can be restated in an even simpler version, a version that highlights the symmetric pairs and preserves the original denominator, that is, the number of pairs in the population:

$$\text{GMD} = \frac{1}{N(N-1)/2} \sum_{j=1}^{N/2} [(N+1-2j) \cdot (X_{N+1-j} - X_j)] \quad (e)$$

The terms in the summation are the absolute differences between the elements of some very special pairs—those pairs whose elements

have rank-order statistics that are equidistant from the rank-order statistic of the median score—and the weight of these special pairs varies with the distance of their rank-order statistics from the median's rank-order statistic, being largest for the pair of extreme scores ($X_N - X_1$). In fact, the weight attached to each absolute difference in the summation is itself the absolute difference between the rank-order statistics of the elements of the pair. That is to say, each of the special symmetric pairs in the summation is represented by the product of the absolute difference between the order statistics and the absolute difference between the rank-order statistics.

Thus, we may remark that the Gini's Mean Difference is exquisitely sensitive to the range of the distribution and to the dispersion about the median.

By algebraic manipulation of formula (e), we can obtain many equivalent expressions, each highlighting an interesting aspect of the Gini's Mean Difference. For example, I have obtained a formula that expresses the numerator of formula (e) for the GMD as a joint function of the signed deviations of the order statistics from the arithmetic mean and the signed deviations of the corresponding rank-order statistics from the median's rank. I have obtained another formula that expresses the numerator as a joint function of the signed deviations of the order statistics from the median and the signed deviations of the corresponding rank-order statistics from the median's rank. But due to space limitations, I present only two more equivalent expressions for the Gini's Mean Difference.

c. *The simplest expression.* Both the formulas that express the Gini's Mean Difference in terms of the arithmetic mean and in terms of the median reduce to the following formula, which I regard as computationally simplest:

$$\text{GMD} = \frac{2 \sum_{i=1}^N ix_i - \bar{x} N(N+1)}{N(N-1)/2} \quad (f)$$

where the x_i are the order statistics and the i are the rank-order statistics. The corresponding formula for the Gini Index of Concentration is even simpler:

$$\text{GIC} = \frac{2 \sum_{i=1}^N ix_i}{N(N-1)\bar{x}} - \frac{N+1}{N-1} \quad (g)$$

This may be the formula that Allison intended to give in his incorrect formula (4).

d. *The proportions formula.* By algebraic

manipulation of formula (f) and using the formula for the sum of the set of positive integers from 1 to N , I have also obtained a formula that uses the proportions occurring above and below each score instead of the rank-order statistics. This formula can then be restated to give the correct expression for the Gini's Mean Difference of a pooled population consisting of several equal distributions, each distribution located at a different point along the x axis. Allison (1978:876-7) discusses this special case, but his formula (24) for the Gini Index of Concentration is incorrect. The correct formula, using his notation (i.e., "where q_j is the proportion that are in groups with means less than \bar{X}_j and r_j is the proportion in groups with means greater than \bar{X}_j "), is:

$$\text{GIC} = \frac{\sum_{j=1}^J \bar{X}_j p_j (q_j - r_j)}{\bar{X}} \times \frac{N}{N-1}. \quad (\text{h})$$

That is, Allison's formula (24) was lacking the factor $(N/(N-1))$. This formula can also be stated in terms of frequencies rather than proportions.

3. The Upper Bound of the Gini Index of Concentration

Allison (1978:869) states that "in finite populations or samples, the Gini index has an upper bound of $1-1/n$." That is incorrect. The upper bound is indeed "reached when one individual has everything and everyone else has nothing." But the value of the Gini Index in such a case is independent of N and is exactly one. Using formula (e), we obtain this result as follows:

$$\text{GIC} = \frac{(X_N - 0)(N-1)}{N(N-1)/2} \div 2\bar{x}.$$

Since the amount held by the N th individual is also the total amount,

$$\text{GIC} = \frac{2\sum x}{N} \times \frac{1}{2\bar{x}},$$

and since the total amount divided by N is equal to the arithmetic mean,

$$\text{GIC} = 1.$$

4. Sensitivity to Transfers

Allison (1978:868) states that the "Gini index is peculiar in that its sensitivity to transfers depends on individuals' ranks rather than their numeric scores" and offers an algebraic ex-

pression for the difference between the values of the Gini Index before and after a transfer of h units from x_i to x_j . But formula (9) is accurate only for the special case in which the rank-order statistics of the parties to the transfer do not change after the transfer. Often the parties to the transfer do acquire new ranks after the transfer; also, a change in the rank of either party to the transfer may occasion a change in rank for one or more other individuals. Using formulas (f) and (g), we see that these changes must be reflected in the summation term in the numerator, for every term in the summation corresponding to an individual whose rank or whose score changes also must change.

The sensitivity to transfers is an appealing way of examining sensitivity to the shape of a distribution. For example, notice how the bar graph of a discrete distribution changes as a result of just one transfer: four of the bars or rods change height.

5. The Gini's Mean Difference and the Variance

Allison (1978:870) suggests defining "a general family of inequality measures that includes both the Gini index and the coefficient of variation," and offers a formula (12) to show their relationship. But formula (12) is based on formula (3), which is incorrect, and hence does not apply to the Gini Index.

It should be pointed out here that while Allison's (1978:870) formula (11) for the population variance is correct, his verbal description refers to quite a different formula. Formula (11) for the population variance is the sum of the pairwise squared differences, divided by N^2 , or alternatively, and analogously to formula (c) above, twice the sum of the pairwise squared differences, divided by $2N^2$. His verbal description, "one-half the average squared difference between all pairs of individuals," correctly describes another formula, the formula for the sample's minimum variance unbiased estimator of the population variance, when the population mean is unknown. Thus, while the numerator, the sum of the pairwise squared differences, is the same in both formulas, the denominator is different; in the formula for the population variance the denominator is N^2 , and in the formula for the sample estimator of the population variance, population mean unknown, the denominator is $(N(N-1))$. (See van der Vaart, 1958:295-6.)

What is the relation between the variance and the Gini's Mean Difference? van der Vaart (1968:253-5) shows that the Gini's Mean Difference and the variance are distribution-specific functions of each other. That is, there

is no general relation between them. If we compare distributions of different functional forms, we well may find that one has the smaller variance but another has the smaller Gini's Mean Difference. Only within distributional family are all measures of inequality monotonic functions of each other.

Moreover, there is an interesting case in which the variance remains constant while the GMD varies. Consider a discrete distribution of any size N and any shape whatsoever, with a given value of the population variance and a given value of the Gini's Mean Difference. If we then pool k identical distributions, the variance remains constant but the Gini's Mean Difference grows smaller. This is because the Gini's Mean Difference is sensitive to every pair, and introducing identical scores means introducing some pairwise differences of value zero to the numerator.

6. An Interpretative Note

Measures of inequality differ from each other in many ways. In particular, their sensitivities to the location, scale, and shape of the distribution, to whether the data are treated as discrete or continuous, to whether the set of data is regarded as a sample or as a population, and to the size of the sample or population can vary greatly. It is most important to become familiar with the properties of many measures of inequality, to learn their peculiarities and idiosyncrasies, to come to know how they behave under a variety of conditions. For the task of the social scientist is not so much to choose among them one to use in every case. Rather the task is to fit the choice of inequality measure to the particular problem under study. The task is to find for each social dependent variable of interest that particular manifestation of inequality that is most highly related to it, and to find for each manifestation of inequality the best predictor variables. It well may be the case that some social phenomena will be seen to vary with the Gini's Mean Difference, others with the Gini Index of Concentration, and others with some other of a large number of measures of inequality.

REPLY TO JASSO*

Jasso claims that all my formulas for index are erroneous because they have the denominator rather than $N(N-1)$. Both versions of the Gini index have their way into the statistical literature; neither one can be said to be incorrect. Nevertheless, for reasons I will explain most sociologists, economists and statisticians who have discussed the Gini index have chosen the definition that is identical or equivalent. (See, for example, Rothschild and Stiglitz, 1973; Dasgupta et al., 1973; Fienberg, 1973; Blau, 1977; Waldman, 1977).

The alternative formulas stem from the ambiguity that arises in defining the Gini index for finite populations. Verbally, the Gini index may be defined as the average of the squared differences between all pairs of scores, divided by twice the mean (a definition which I accept). The question comes down to computing the average, how many pairs of scores are there? The answer depends on whether we allow a score to be paired with itself or only consider pairs of distinct scores. This dilemma which has been aptly stated by Jasso and Stuart (1977:47-8):

[Gini's coefficient of] mean difference is the average of the differences of all the possible pairs of variate values, taken regardless of significance.

* Direct all communications to: Paul Allison, Department of Sociology, Cornell University, Ithaca, NY 14853.

coefficient with repetition each value is taken with itself, adding of course nothing to the sum of deviations, but resulting in the total number of pairs being N^2 . In the coefficient without repetition only distinct values are taken, so that the number of pairs is $N(N-1)$.

Note that this distinction is closely related to the question of sampling with or without replacement. As Jasso observes, Gini's mean difference (the numerator of the Gini index) may be interpreted as the expected value of the absolute difference between two randomly chosen individuals. This formulation is ambiguous, however, since it does not indicate whether or not the first randomly chosen individual is "replaced" before choosing the second. If replacement occurs, we then have the possibility that the same individual will be drawn twice, in which case the difference will be zero.

Intuitively, it might seem more reasonable to exclude pairs in which a score is paired with itself because the difference is *necessarily* zero. Yet there are at least two reasons for including such pairs and, hence, using the definition with N^2 in the denominator. First, the Gini index often is defined as twice the area between the Lorenz curve and the line of perfect equality (see section 4 in my original article). In order for the algebraic formula to be consistent with this geometric definition, it is necessary that the denominator have N^2 rather than $N(N-1)$. Second, Jasso's version of the Gini index does not possess an appealing property which Sen (1973) calls the population symmetry axiom. This notion can be expressed as follows. Suppose we have two populations of equal size and identical distributions of income. Using either formula, the Gini index will be the same for both populations. But what if we combine the two populations? Population symmetry requires that the Gini index for the combined population be the same as the Gini index for each population taken separately. My formula has this property but Jasso's gives a lower value for the combined population.

Both of these points can be demonstrated heuristically by considering upper bounds on the Gini index. As Jasso shows, her formula has an upper bound of one, while my formula has an upper bound of $1 - 1/N$. Thus, in a two-person population in which one person has all the income, my formula gives a Gini index of one-half while Jasso's formula gives a value of one. Consider the Lorenz curve for this two-person population (Figure 1). Since the total area of the square in Figure 1 is one, the area between the Lorenz curve and the line of perfect equality must be one-fourth. Hence, the Gini index is one-half, which is consistent with my formula but not with Jasso's.

Figure 1. Lorenz Curve for a Two-Person Population

Now suppose we have another two-person population with the same distribution of income. If we combine these two groups, we get a four-person population in which two people have no income and two people have equal positive shares. Since a single person no longer controls all the income, Jasso's formula does not reach its upper bound of one. It is not difficult to show, however, that my formula still gives a Gini index of one-half.

Sections 1, 2, 3 and 5 of Jasso's comment all rest on the presumption that N^2 is the wrong denominator. In section 4, however, she correctly identifies a problem with my formula (9) which gives a change in the Gini index resulting from a transfer from one individual to another. Specifically, the formula is only valid for the special case in which the transfer is not so great as to change the rank order of either individual.

In section 6, Jasso argues that different measures of inequality may be appropriate for different substantive problems. This is good advice, but Jasso goes too far when she suggests that the choice be based principally on observed covariation ("The task is to find for each social dependent variable of interest that particular manifestation of inequality that is most highly related with it . . ."). In fact, a strictly empirical approach can easily produce misleading or artifactual results. Suppose, for example, that we used the standard deviation to compare income inequality across different census tracts. Almost surely we would find a high correlation between the standard deviation and the mean or any other variable strongly associated with the mean. But this is merely a consequence of the scale dependence of the standard deviation. The more appropriate

ate scale invariant measures like the Gini index or the coefficient of variation probably would produce lower correlations, but this is hardly a mark against them. While empirical results should not be discounted, the first task is to identify those measures on inequality that are *theoretically* appropriate for the problem at hand.

Before concluding, I would like to point out a typographical error that occurred in my formula (17) for Atkinson's measure of inequality. That formula should have been:

$$A = 1 - \left[\frac{1}{n} \sum_{i=1}^n \left(\frac{x_i}{\mu} \right)^{1-e} \right]^{\frac{1}{1-e}}$$

In the published version, the $1/n$ was transposed to $n/1$ and placed outside the brackets.

DETERRENCE AND SOCIAL CONTROL: A REPLY TO GRASMICK AND MCLAUGHLIN*

(ASR APRIL, 1978)

I am taking this opportunity to correct Grasmick and McLaughlin's (1978) misleading and erroneous comments on my article on de-

terrence theory (Silberman, 1976). These comments were based on misinterpretations and distortions of the findings presented in my article and in some of the sources they relied on.

Grasmick and McLaughlin properly place my article on deterrence theory within the general framework of the study of social control. Although they are correct when they assert that this article represents the first deterrence research to be published in the *ASR* or *AJS*, it should be pointed out that it is not the first research on the role of coercion in the social control process published in the *ASR*. (The *AJS*, I believe, historically has avoided this area of research.) A few articles expressing two different, if not competing, conceptualizations of the role of coercion in society have been published in the *ASR*. Articles written within, or influenced by, the framework of Etzioni's (1961) compliance theory were published in the late sixties (see Julian, 1966; Adamek and Dager, 1968; Warren, 1968). These articles focused on the distribution of conforming and alienative responses to the use or threatened use of coercive power. On the other hand, Snyder and Tilly (1972), employing a conflict perspective, viewed the use or threatened use of coercive power as a central feature of the struggle among competing groups for control over governmental institutions. In other words, there is a growing, empirically grounded, social control literature, of which deterrence research is a "significant" part. Deterrence research (my own included) focuses on the conforming response to coercive power under specified conditions. Of equally important interest in a theory of social control are studies of the alienative response to coercive power, the use of coercion in response to alienation, and the use of coercion as an expression of political conflict.

In order to be perfectly clear about the source of disagreement between myself and my commenters, I shall proceed by listing and discussing each point in the sequence presented in the review.

- (1) Crime statistics do reveal this pattern of zero-order correlations [between severity of punishment and crime rates only for homicide], but Silberman fails to note that for nearly all major felonies there is a substantial negative zero-order correlation between certainty and severity among aggregates. Logan (1972) discovered that when certainty (conviction rate) is controlled, severity (median sentence) has a weak to moderate negative partial correlation with the crime rate for nearly all major felonies. (p. 273)

A closer reading of Logan's (1972) work reveals substantial and significant partial corre-

* Direct all communications to: Matthew Silberman; Department of Sociology; Bucknell University; Lewisburg, PA 17837.

lations between severity and crime rate for only *two* offenses, with certainty of punishment controlled for: homicide and assault. Logan's analysis of the correlations between severity and crime rate under conditions of high and low certainty yields consistent negative correlations of substantial magnitude *only for homicide*. Furthermore, the Logan study is a replication of an earlier one by Tittle (1969) which I did cite in my article (Silberman, 1976:443-4). Tittle (1969:419) points out that under "constant levels of certainty . . . severity of punishment has little consistent independent or additive effect." The zero-order negative correlation between certainty and severity among (state level) aggregates reported by Logan (1972:70), but not by Tittle (1969:422), has little bearing on our further understanding of deterrence. The existing evidence, including that which Grasmick and McLaughlin cite, could hardly support their misleading conclusion that severe punishment is a deterrent for "nearly all major felonies." In fact, the evidence, my own included, supports the notion that to the extent that severe punishment acts as a deterrent, its effects are limited to crimes against persons (Silberman, 1976:447, 458-9).

(2) This finding, that aggregates which have severe penalties tend to have low conviction rates, has been of interest to researchers (see Bailey and Smith, 1972). (p. 274)

The above statement is terribly misleading. Bailey and Smith's study is not on the deterrent effects of severity of punishment. Their study examines the relationship between the severity of punishment and its certainty. They may be "interested" in that aspect of deterrence theory which suggests that severe punishment deters crime (Bailey and Smith, 1972:538), but they do no research on the subject.

(3) Ross (1976) has proposed a hypothesis which he calls the "neutralization of severe sanctions" to explain this kind of phenomenon. (p. 274)

The "kind of phenomenon" that Grasmick and McLaughlin are trying to explain is the alleged interaction of severity and certainty of punishment in effecting reduced crime rates at the aggregate level. Ross' (1976:404) argument is *not* that severity of punishment has a deterrent effect under specified levels of certainty of punishment, but that increasingly severe official penalties are *neutralized* by discretionary actions at various stages of the criminal justice process. Whereas this may account for a negative correlation between severity and certainty of punishment, Ross (1976:404) points out that his analysis "failed to produce evidence that the change [unusually stringent penalties] promoted higher safety." He later (1976:412)

adds, "In none of the studies cited could any deterrent effect of increased penalties be proved." Since Ross concludes that in the area of traffic safety there is no evidence to support the deterrence argument as far as severity of punishment is concerned, with or without controlling for certainty of punishment, I must conclude that Grasmick and McLaughlin have misinterpreted the findings and implications of the Ross study.

(4) The "credibility of severe sanctions" hypothesis has been offered at the individual level in previous writings (see Tittle and Logan, 1973:384), but Silberman does not test it. This hypothesis states that perceived severity of punishment has a deterrent effect only when the perceived certainty of punishment is high. . . . Since the publication of Silberman's article, Teevan (1976) has presented evidence supporting this hypothesis. (p. 274)

Tittle and Logan (1973:384) state that "sanctions may have some deterrent effect when the certainty of imposition is reasonably high but that severity of sanctions in the absence of certainty has little bearing on deviance." However, the evidence to support this hypothesis is weak. The Ross et al. (1970) study cited by Tittle and Logan demonstrates the effectiveness of legal reform on accidents due to drunk driving, but the certainty of detection and severity of sanctions were increased simultaneously. Consequently, it is not possible to determine whether it is certainty alone, or severity alone, or the combination of both which deterred drunk driving.

The Teevan (1976) study presents far less support for this hypothesis than Grasmick and McLaughlin would have us believe. The zero-order relationship between perceived certainty and the likelihood of committing two offenses, marijuana use and shoplifting, are described as significantly negative (but weak) and nonsignificant, respectively. Teevan (1976:157) also reports that there is "no support" for the severity hypothesis. Only the gammas describing the negative relationships between perceived severity and the likelihood of committing the two offenses for those "who perceive moderate or higher certainty of punishment" are reported. As Teevan points out (1976:157), these relationships are *not significant* since gammas "are sensitive to small N's and unequal marginals and should be *interpreted with caution*" (emphasis mine). A further note of caution: the relationship between perceived severity and criminal behavior for those who perceive low certainty of punishment is not reported or described for either offense. This selective reporting of his results makes Teevan's article difficult to evaluate. How "credible" is an hypothesis based upon such evidence?

I did not report any evidence to support an

interaction model testing the "credibility" hypothesis, because there was no such evidence to report. A test of the interaction of certainty and severity on criminal involvement using the procedures followed in the studies cited above is presented in Table 1. Just as the zero-order correlation between severity and criminal involvement in general is nonsignificant and positive (as Grasmick and McLaughlin note on p. 274), the correlations between severity and criminal involvement under conditions of high and low certainty are also nonsignificant and positive. A further examination of the evidence for specific offenses reveals no support for the credibility hypothesis (see Table 1).

(5) Silberman's measure of perceived severity of legal punishment seems [sic] invalid. . . . His measure is whether or not the respondent believed he would receive the state's maximum penalty if convicted of committing the offense. But, there is evidence from other research (California Assembly, 1968) that people vary in what they believe is the legal maximum penalty for particular offenses, and Silberman's measure does not take into account this variation. (p. 274)

There are three types of measurement validity (see Phillips, 1971:197-201): (a) face validity, the measure clearly initiates what is intended "on the face of it," as in an operational definition; (b) criterion validity, the measure correlates with another "accepted" measure of the same phenomenon; and (c) construct validity, the measure yields the expected theoretical prediction; i.e., it yields the same predictions as other measures of the same phenomenon. Grasmick and McLaughlin, assuming that "Silberman's" measure does not differentiate between those who may perceive the maximum penalty to be a \$100 fine and those who perceive the maximum to be six months in jail, limit their criticisms to the first

type. I will address this issue as well as the other two.

First, it should be pointed out (as I did in my article; see Silberman, 1976:444) that the measure of perceived severity is not "mine," but one used in previous research (see Waldo and Chiricos, 1972:524-6, for a full discussion of the rationale behind this measure). On its "face," this measure is designed to evaluate the *relative* severity of the perception of the threat of punishment, regardless of the *accuracy* of threat perception. What Grasmick and McLaughlin would have us do is introduce the "accuracy" dimension into the measure. It would make sense to introduce this dimension as a *separate variable* in the analysis, rather than confound the measurement of perceived severity. In discussing future research, I point out (Silberman, 1976:450) that the relationship between actual and perceived threats of punishment must be taken into account in order to understand fully the deterrence process. Accuracy of perception should be an important intervening variable in this process.

Since there is little consensus in the deterrence literature regarding an "accepted" measure of perceived severity, it is difficult to assess the criterion validity of the measure used in my study. The fact that it is almost identical to the measure used in the Waldo and Chiricos (1972:531) study lends it some credibility. The questions were identical: "If you were convicted of committing [offense], how likely would you be to get the maximum [state] penalty?" However, in their study, three choices were available to the respondents, "likely," "50/50," and "unlikely," whereas in my study, four choices were available, "very likely," "likely," "unlikely," and "very unlikely." It is reasonable to assume that were both measures used in the same study, the

Table 1. Point-Biserial Correlations between Severity Index and Criminal Involvement with Certainty Index Controlled for

	Without Control ^a (N=174)	Low Certainty ^b (N=84)	High Certainty ^b (N=89)

^b This variable is dichotomized above and below the mean.

correlation between them would be very strong.

As far as construct validity is concerned, the predicted effect of perceived severity on criminal involvement is generally consistent with findings using similar or other measures of perceived severity and measures of actual severity of punishment. Such inconsistencies that do exist can be resolved on theoretical and methodological grounds (see Silberman, 1976:458-9). In general, it seems that severity of punishment is associated with the deterrence of crimes against persons under specific conditions.

(6) He [Silberman] offers the hypothesis that a high level of involvement with such peers [who engage in criminal behavior] . . . "may reduce the effect of threat of punishment" (p. 443), but, offers no rationale for the hypothesis. (p. 274)

This statement is taken completely out of context, and consequently, misrepresents what I wrote. In discussing untested "theoretical speculation about the nature of the interaction among variables associated with the deterrence of criminal behavior" (Silberman, 1976:443), I cite Tittle and Rowe (1974:461) who wrote that " 'differential association' might be considered a condition which reduces fear of sanction." My full statement was that "*differential association*, the process by which individuals learn criminal behavior through involvement with others who define such behavior favorably, *may reduce the effect of the threat of punishment*" (Silberman, 1976:443; emphasis added). Since no support was found for this argument, i.e., the effect of the interaction between certainty of punishment and involvement with criminal others on the degree of criminal involvement was not significant (see Silberman, 1976:450, Table 4b), no further attention was paid to this argument in the article.

(7) Three hypotheses concerning characteristics of peers as a conditional variable have appeared in the literature, and each of these focuses on the role of threat of social disapproval from peers as a mechanism of social control. (p. 274)

After recognizing correctly that the variable *peer involvement* used in my study was a measure of "involvement with peers who engage in criminal behavior" (p. 274), Grasmick and McLaughlin conveniently redefine peer involvement in terms of the absence of the "threat of social disapproval" from "conventional" others (p. 275). Instead of pointing out that I did not measure "threat of social disapproval," my findings were distorted to test hypotheses they were not designed to test. The threat of disapproval from "conventional" others is surely not equivalent to the absence of encouragement by criminally involved

others to engage in criminal behavior. In fact, we can easily imagine circumstances in which individuals simultaneously experience support for "criminality" and "conventionality" from criminally involved and conventional "peer" groups, respectively.

Consequently, Grasmick and McLaughlin's entire discussion of the "hypotheses" and their reanalysis of the effects of the interaction between peer involvement and certainty of punishment (pp. 274-6) and the interaction of peer involvement and moral commitment (p. 277) on criminal involvement is rendered meaningless.

(8) Silberman's test of the interaction of certainty and peer involvement is confounded by a simultaneous control for morality. . . . Silberman's test of the proposed conditional relationship [the interaction of moral commitment to the law and threat of legal punishment in the deterrence process] is confounded by a control for another variable [Peer Involvement]. (p. 275)

Grasmick and McLaughlin apparently do not know how to interpret analysis of variance. If they had reported the findings presented in Table 4b (Silberman, 1976:450), they would have noted that their "conclusions" (based on three lower-order tables "reconstructed" from my original table) concerning the "additive" effects of certainty and peer involvement (Table 1, p. 275), the interaction effect of moral commitment and certainty (Table 2, p. 276), and the interaction effect of moral commitment and peer involvement (Table 3, p. 277) were redundant. Table 4b, a saturated model of the three-way analysis of variance for three dichotomous independent variables, reveals that there is no significant interaction between certainty and peer involvement, nor is there a significant three-way interaction among morality, certainty and peer involvement. The "main" effects of morality, certainty, and peer involvement on criminal involvement are all statistically significant, as are the interaction effects of morality and certainty, and morality and peer involvement. The advantage of the "simultaneous" control for third variables is the enhanced ability to explain the interrelationships among all the variables. Furthermore, as we have seen, it is a far more efficient way to present the data. It is only because there are "simultaneous" controls that we can conclude that moral commitment interacts *independently* with certainty and peer involvement to affect the degree of criminal involvement.

(9) Silberman commits several serious errors in the use of path analysis. . . .

(a) he claims that . . . [the individual level data] "fit a causal chain model" (p. 448)

(b) Silberman at least should have noted that

path analysis assumes all effects of independent variables are additive. . . .

(c) In the offense-level path diagram (p. 452), morality suddenly becomes an intervening variable between certainty and percent committing the offense, while in the individual-level diagram both morality and certainty are presented as exogenous. . . .

(d) Although [the offense-level analysis is] based on four independent variables for only nine cases . . . , *he does not hesitate* to draw substantive conclusions [emphasis mine]. . . .

(e) He is oblivious to a glaring case of multicollinearity. (p. 276)

Grasmick and McLaughlin fail to recognize that the central point and purpose in using path analysis is to represent theoretically grounded causal models. As Duncan, (1966:16) pointed out in his definitive article on the subject, such an analysis is "meaningless" unless it reflects "explicit assumptions" derived from the "theoretical structure" of the problem. Path analysis is "invaluable in rendering interpretations explicit, self-consistent, and *susceptible to rejection by subsequent research*" (Duncan, 1966:1; emphasis mine). This is not only true in path analysis, but in multiple regression in general (Gordon, 1968), of which path analysis is a special case. Gordon (1968:592) points out that "multicollinearity" is essentially a problem of "substantive interpretation," an issue that is usually ignored in "statistics texts." When the correlation between independent variables is very high, the interpretation of the model "depends upon the causal ordering of the variables" (Gordon, 1968:594; for a discussion of the problems associated with multicollinearity in causal models in general, see Blalock, 1963). Consequently, a limited number of causal models may fit the available data. The choice of the best-fitting model must be based on both mathematical and theoretical grounds.

In my article, I reject a "chain model" principally on theoretical grounds (Silberman, 1976:449; see [a] above). Such a model would include the assumption of dependency among the four "independent" variables, each of which would become a dependent variable in a series of regression equations comprising the complete path model. This assumption is explicitly rejected. Furthermore, the inclusion of a fifth variable, criminal involvement, as a dependent variable in the model makes it clear on empirical grounds that a "causal chain" does not describe the data well at all. Consequently, the path model reduces to a "single-equation model in which all four variables are treated as exogenous" (p. 276).

As I point out in my article, the path model described in Figure 1 (Silberman, 1976:450) "is a pictorial representation of the linear, *additive*,

causal relations described in the preceding paragraphs" (Silberman, 1976:449; see [b] above). I add (Silberman, 1976:449), "Testing for interaction is essential to the discovery of the contingencies associated with the propositions of an axiomatic theory (Costner and Leik, 1964)." The analysis of variance described above was designed to test for this interaction.

On the offense level of analysis, all "independent" variables are no longer treated as exogenous, because such a treatment would not be consistent with the data: peer involvement is uncorrelated with any of the other variables and the zero-order intercorrelations among the remaining three independent variables are very strong. In the model treating the remaining three variables as exogenous, the deterrent effects of severity and certainty disappear. Consequently, a model assuming that at least one of the variables is not exogenous is consistent with the data, and a model in which moral commitment is the intervening variable fits the data best (see Silberman, 1976:451; and [c] above). The reader is cautioned at least twice on the "tentative" nature of conclusions based on the small number (nine) of offenses involved in the offense-level analysis (see Silberman, 1976:451, 453; and [d] above).

When the correlations among the independent variables are very strong, as they are on the offense level of analysis, the standard errors of the path coefficients become large, making it difficult to select causal models on strictly empirical grounds (Blalock, 1963:233-7; Gordon, 1968:568; Wonnacott and Wonnacott, 1970:59-62). This is called "the problem of multicollinearity" (Wonnacott and Wonnacott, 1970:61). From a strictly mathematical point of view, the independent variables in such a case are "causally equivalent" (Gordon, 1968:594); i.e., given sampling variation, each variable could substitute for the other equally well in the model. However, the variables in the model are not theoretically equivalent; i.e., they are conceptually distinct and theoretically independent ideas. It might be argued that respondents to a questionnaire may have similar understandings of the independent variables such that the underlying dimension is the same, but this is clearly not the case here. On the individual level of analysis, these variables are *not* highly intercorrelated. Only when *aggregated* are the correlations strong. In other words, the evidence supports the notion that the independent variables are conceptually distinct; i.e., not equivalent. The multicollinearity problem implies that different causal models may fit the data equally well, given sampling variation caused by large standard errors. While this is true mathematically speaking, theoretical considerations may

rule out certain models and favor others. The model presented in my paper not only fits the data best *for this sample*, but it makes the most sense theoretically (see pp. 453–60; and [e] above).

Since the publication of my article, Erickson et al. (1977) discussed the multicollinearity issue at length in their article on the relationship between perceived certainty of punishment and self-reported criminality for 15 types of offenses among high school students in Arizona. The data they presented differ in one important respect from mine: the coefficients they report are relatively weak, whereas the path coefficient between moral commitment and criminal involvement in my study is strong ($-.90$). As a noted econometrician points out,

The effect of an explanatory variable may be sufficiently strong for the estimated coefficient to be statistically different from zero in spite of the effect of collinearity in increasing the standard error (Johnston, 1972:163).

Furthermore, the standard error of the path coefficients *decreases* as the amount of unexplained (residual) variance decreases (see Johnston, 1972:161). Unfortunately, it also *increases* with decreasing sample size and increasing number of variables, a problem already noted above and in the original article (see Johnston, 1972:161–2). Despite the problem of multicollinearity, the strong negative path coefficient between moral commitment and criminal involvement, and the *relatively* small residual, lend further support for the model. The problem of sample size is inherent in an analysis based on the offense as its unit of analysis. There are a limited number of offenses that can be studied in the context of self-reported surveys, and there is a limited amount of information on different types of offenses from official sources. Despite these inherent problems, and with the appropriate notes of caution, we should continue to use the analytic tools that are available to us as best we can.

CONCLUSION

By quoting out of context, misunderstanding and misinterpreting the findings reported in my article, Grasmick and McLaughlin are able to derive a model of social control that is not supported by my article nor substantiated by their comments on it. Their model has four basic flaws:

(1) it reflects a misunderstanding of the analytic nature of the variables measured; e.g., the dependent variable in the model is simply conformity/deviance rather than degree of

criminality measured in terms of the number of offenses committed;

(2) it reflects confusion about the nature of interaction effects;

(3) it includes the notion of “threat of social disapproval” by conventional others, which was unmeasured in my study (although they claim that it was); and,

(4) it ignores the level of analysis issue.

These flaws and their theoretical implications are addressed in sequence below.

(1) Unlike Grasmick and McLaughlin, I do not stress the notion of “internalization,” nor a simple dichotomy of conformity/nonconformity in my analysis. Theirs is a model based on the assumption that individuals engage in deviant behavior because they are “inadequately socialized”; mine is not. According to Grasmick and McLaughlin, there are “good guys,” those that “conform because they have internalized the law [whose] conformity is independent of threats of legal punishment or social disapproval” (p. 277), and “bad guys,” who can only be deterred by the threat of force or disapproval from peers; i.e., they have no conscience. In citing Mead’s notion of “taking the role of the generalized other,” I stress the importance of the individuals’ response to “the society around him. . . . A sense of moral commitment should theoretically be organized around a *set* of societal regulations” (Silberman, 1976:456). What is “internalized” is the approving/disapproving responses of others who support (regulate) conventional behavior (the rules of the game). Expressions of moral commitment reflect the influence of “conventional” others. Furthermore, individuals are conceived of here to vary along a dimension reflecting the *degree* of commitment to “conventionality.” Dichotomizing above and below the mean, as I do at one point, does not imply that all those above the mean have “internalized the law.” Similarly, individuals are not conceived of as either conforming or nonconforming, but varying along a dimension of criminality from very little to a great deal. Nearly all (97%) of the respondents admitted to *some* criminality.¹ The issue is one of degree of conventionality (morality) and criminality (legality) and the relationship between these variables.

(2) The relationship between statistical interaction and substantive theory is not nearly

¹ As many as 78% admitted to committing at least one jailable offense from a list including disorderly conduct, drug use (excluding the illegal consumption of alcohol), theft, vandalism, and assault; 18% more admitted only to the illegal (under age) consumption of alcohol, a crime which only occasionally produces arrests.

as simple as Grasmick and McLaughlin suggest (see Southwood, 1978). There are a variety of theoretical interpretations possible for any given finding of statistical interaction. The appropriate theoretical interpretation depends largely on the method of analysis employed. The theoretical model Grasmick and McLaughlin employ is what Southwood (1978:1163-9) calls a "conduciveness" model in which the existence of the effect of an independent variable depends on the presence (or absence) of some specific condition associated with a third variable. The kinds of theoretical assumptions Grasmick and McLaughlin make regarding the nature of law and morality, i.e., that there are conformers and nonconformers, those who are moral and those who are not, those who violate the law and those who do not, are not consistent with the methodological approach used in the original analysis nor in their reanalysis of the data. Consequently, the model of social control they posit based on these assumptions is not consistent with the actual results. The evidence is consistent with an interaction model in which "the linear relationship of a dependent variable, Y, with an independent variable, X, is itself a linear function of [a third variable]" (Southwood, 1978:1163).

(3) A measure of moral commitment is a better indicator of the "threat of social disapproval" from conventional others than a measure of involvement with deviant others. Such an interpretation yields a model in which the negative (deterrent) effect on criminal involvement of certainty of punishment increases with decreasing conventionality (moral commitment); i.e., the effects of certainty and threat of social disapproval on criminality are interactive rather than "additive" as Grasmick and McLaughlin assert.

(4) In describing the analysis of the offense-level data as invalid, and ignoring that part of the analysis which examined interaction among the variables, Grasmick and McLaughlin conveniently neglect a central criticism of the deterrence literature that I was addressing in such an analysis. The literature is replete with examples of the "ecological fallacy," the inference to one level of analysis from data based on another. I believe that I demonstrated successfully that no matter what model might best describe the interrelationships among the variables on the offense level of analysis, it would not be the same as one describing these interrelationships on the individual level. In the case of offenses for which there is strong moral commitment in general (e.g., assault), the correlation between perceived certainty of punishment and criminal involvement is significant and negative,

whereas in the case of offenses for which there is little moral commitment in general (e.g., drinking under age), the correlation between perceived certainty and criminal involvement is not significant. Similarly, in the case of offenses for which there is strong moral commitment in general, the correlation between peer involvement and criminal involvement is significant and positive, whereas in the case of offenses for which there is little moral commitment, this correlation is not significant.

In general, the strength of the effects of the independent variables (excluding perceived severity) *increases* with increasing levels of moral commitment among offenses, whereas the strength of the effects of the independent variables *decreases* with increasing moral commitment among individuals. This suggests that individuals who are *less* morally committed in situations where supports for conventionality are generally strong are most deterred by the perceived threat of certain punishment and most encouraged by support for criminality by deviant others. In situations where there is little *general* support for regulation, the threat of punishment and the support of deviant others has *relatively* little effect on involvement in acts that are legally, but not morally, proscribed.

These data are consistent with a theory of differential association, differential opportunity structures, and differential law enforcement discussed more fully in the concluding section of my article (Silberman, 1976:458-60).

ITEMS (Continued)

the University of Chicago. He is applying network analysis to the study of community decision-making. He also is studying the social structure of the legal profession in a major urban bar. In 1976 he authored (with Franz U. Pappi) *Networks of Collective Action* (Academic Press). He soon will publish *The Social Structure of the Legal Profession* (authored with John P. Heinz; forthcoming, American Bar Association). PETER V. MARSDEN is Assistant Professor of Sociology at the University of North Carolina. His research centers on a development of modifications of Coleman's purposive action model to allow for constraints imposed by social networks.

■ GARY ALAN FINE (Small Groups and Culture Creation) is Assistant Professor of Sociology at the University of Minnesota. Fine's current research is on the relationship between social structure and artistic production. In particular, he is examining the position of chefs as artists, and of gourmet cooking as artistic work.

■ JOE L. SPAETH (Vertical Differentiation among Occupations) is Associate Professor in the Department of Sociology and Research Associate Professor in the Survey Research Laboratory at the University of Illinois, Urbana. He is completing research on the determinants of earnings and of the sex gap in earnings and on-job satisfaction among college graduates. He also intends to pursue his interests in occupational stratification.

■ JOHN SEIDLER (Priest Resignations in a Lazy Monopoly) is Associate Professor of Sociology at Ohio State University. His research addresses conflict and structural change among American Catholic priests, from the 1960s through the 1970s.

■ SANDRA L. HOFFERTH (Early Childbearing and Later Economic Well-Being) is Research Associate at the Urban Institute, Washington, D.C. Her research centers on sex differences among non-college-bound boys and girls during the high-school and early post-high-school years. KRISTIN A. MOORE is Senior Research Associate at the Urban Institute, Washington, D.C. She is studying policy determinants of teenage childbearing. Both Hofferth and Moore have authored (with Steven B. Caldwell and Linda J. Waite) *Teenage Motherhood: Social and Economic Consequences* (Urban Institute, 1979).

■ J. SCOTT LONG (Entrance into the Academic Career) is Assistant Professor in the Department of Sociology at Washington State University. Long's current research presently proceeds on two paths: 1) the process of stratification in the scientific career; and 2) multivariate statistical techniques. PAUL D. ALLISON is Assistant Professor in the Department of Sociology at Cornell University. With J. Scott Long he is investigating the relationship between university departmental prestige and the productivity of individual scientists. He also is developing new methods for the analysis of event history data. ROBERT MCGINNIS is Director of the Re-

search Program on Social Analyses of Science Systems at Cornell. He is doing research on networks of basic and applied research, researchers, and research organizations in agricultural science.

■ ARLAND THORNTON (Changes in Sex Role Attitudes of Women, 1962-1977) is Assistant Research Scientist, Institute for Social Research, and Assistant Professor of Sociology at the University of Michigan. He is conducting research on sex roles, fertility, female labor force participation, and marital dissolution. DEBORAH S. FREEDMAN is Assistant Professor in the Department of Economics and Research Associate in the Population Studies Center at the University of Michigan. She is studying the interrelation of fertility and economic factors.

■ DAVID F. GREENBERG (A Panel Model of Crime Rates and Arrest Rates) is Associate Professor in the Department of Sociology at New York University. His work focuses on historical change in conceptions of deviance, law, and economic development in the Third World, and on the social psychology of delinquency. He has authored *Mathematical Sociology* (Rutgers University Press, 1979) and *Corrections and Punishment* (Sage, 1977). He plans to publish *Class and Crime: Essays in Marxian Criminology* (Mayfield, forthcoming). RONALD C. KESSLER is Assistant Professor in the Department of Sociology, University of Michigan. His research centers on the structural determinants of psychological well-being and mental illness, and on the role of coping resources in buffering the psychological effects of stressful life experience. CHARLES H. LOGAN is Associate Professor of Sociology at the University of Connecticut. His research interests include deterrence, parole, status offenders, and artifacts in ratio correlation. He has authored *Does Parole Make a Difference?* (with Howard R. Sacks; University of Connecticut Law School Press, 1979).

■ ROBERT M. O'BRIEN (The Use of Pearson's r with Ordinal Data) is Associate Professor and Chairperson of the Department of Sociology at California State College. His research focuses on statistical methodology, the ecological correlates of crime and the determinants of naturalization rates. He will publish (with David L. Decker and David Shicor) *Urban Structure and Victimization* (D. C. Heath, forthcoming).

■ WALTER I. WARDWELL (Comment on Franke and Kaul, ASR October, 1978) is Professor of Sociology at the University of Connecticut. His research centers on the sociology of health-related professions.

■ GUILLERMINA JASSO (Comment on Allison, ASR December, 1978) is Special Assistant to the Commissioner of the U.S. Immigration and Naturalization Service. Her work and interest concentrate on resource distributions and their impact on both social relations and the individual's sense of justice.

AMERICAN SOCIOLOGICAL REVIEW

THE PRESIDENTIAL ADDRESS: MEASUREMENT AND CONCEPTUALIZATION PROBLEMS: THE MAJOR OBSTACLE TO INTEGRATING THEORY AND RESEARCH*

H. M. BLALOCK, JR.
University of Washington

American Sociological Review 1979, Vol. 44 (December):881-894

In one sense the theme of this paper is obvious. Sociologists face extremely tough intellectual and practical tasks owing to the ambitious nature of our common objectives and the complex reality with which we deal. These tasks will require a *concerted* effort of scholars with diverse substantive, theoretical, and methodological interests and persuasions. Yet in many respects we seem badly divided into a myriad of theoretical and methodological schools that tend to oversimplify each other's positions, that fail to make careful conceptual distinctions, and that encourage partisan attacks.

Rather than dwelling on these divisive issues within our profession, it is crucial that we learn to resist overplaying our differences at the expense of common intellectual interests. There will obviously be disagreements over appropriate strategies, as well as ideological and disciplinary differences. But an idealization of conflict and dissensus is self-defeating. Some conflicts will inevitably occur and, if constructively resolved, may result in benefits to the discipline. But I think there has been too great a tendency to exaggerate these benefits, without recognizing the inherent dangers of endless theoretical and methodological debates and a further fractionating of our field.

One particularly disappointing feature of our discipline is that we have not had

the productive interplay between theory and research called for so eloquently by Merton (1968) several decades ago. This interplay, if it ever comes about in a systematic way, will require us to grapple with a number of extremely complex problems that I shall merely list before narrowing my remarks to two issues that illustrate the need for analyses that are simultaneously theoretical and methodological. My list is as follows:

1. Reality is sufficiently complex that we will need theories that contain upwards of fifty variables if we wish to disentangle the effects of numerous exogenous and endogenous variables on the diversity of dependent variables that interest us.

2. Many social changes are either very rapid compared to the intervals of observation or are continuous rather than discrete, so that temporal sequences cannot easily be inferred or linked to given historical events.

3. Realistic models of naturally occurring social phenomena must be nonrecursive or contain highly specific assumptions about lag periods or distributed lags.

4. Many important theoretical variables are highly intercorrelated, though perhaps the empirical associations among them will be underestimated due to random measurement errors. Resolving this multicollinearity problem will require a combination of large samples and good measurement.

5. Human actors and social systems tend to be nonhomogeneous with respect

*Address all communications to: Hubert M. Blalock; Department of Sociology; University of Washington; Seattle, WA 98100.

to parameters in structural equations, implying that they will not respond similarly to changes in other variables. This will have major implications not only for our theories but also for measurement decisions, whenever effect indicators are being used, and for micro-macro analyses where aggregation decisions are needed.

6. Many groups and contexts have fuzzy boundaries. Standards, such as group norms or role expectations, also tend to be imprecise and subject to dispute. Measurement that depends in some essential way upon these fuzzy boundaries or standards thereby becomes exceedingly difficult.

7. The linkage of micro- and macrotheories involving different units of analysis is problematic unless simplifying assumptions can legitimately be made. In particular, aggregation-disaggregation problems are made difficult whenever there are nonnegligible contextual effects, nonlinearities, or unknown measurement errors.

8. All measurement is to some degree indirect and therefore requires untested assumptions of a causal nature, but this problem is especially serious whenever one-to-one linkages between constructs and indicators cannot be assumed, whenever replications under standardized conditions are impossible, whenever homogeneity properties facilitating indirect measurement cannot be assumed, and whenever the ratio of unmeasured to measured variables is high.

9. Given the practical roadblocks to data collection that will continue for the foreseeable future, any piece of research will necessarily involve large amounts of missing information, thereby requiring either implicit or explicit assumptions and the neglect of numerous variables thought to be theoretically important.

Although the development of theory is important in its own right, I believe that the most serious and important problems that require our immediate and concerted attention are those of conceptualization and measurement, which have far too long been neglected. I have reached this conclusion having come at the matter from two very different perspectives. The first is through an examination of the implica-

tions of random and nonrandom measurement errors for data analysis and theory testing, and the second is through frustrating efforts to make sense of the theoretical and empirical literature in one of our substantive fields, that of race and ethnic relations. Both these endeavors leave me with the realization that these conceptualization and measurement problems are much more complex than I had previously thought. In fact they are so complex, and their implications for analysis so serious, that I believe that a really coordinated effort in this direction is absolutely essential.

Clearly, we need theories that are sufficiently general to integrate our fragmenting discipline into reasonably coherent bundles. These theories must be precise enough to yield predictions that are both falsifiable and that extend beyond common sense. We might hope that our theories and analyses can also be reasonably simple, but for reasons elaborated elsewhere (Blalock, 1979) I do not believe we can simultaneously achieve generality, accuracy, and simplicity. Therefore we must give up one or another of these desirable characteristics. If we opt for simplicity, and if social reality is in fact complex, we shall inevitably be misled.

Given the limitations imposed by our meager resources and missing data, it is crucial that we carefully examine what these imply in terms of linkages between theory and research. Missing variables force us to use highly indirect measures, improper aggregation operations, and crude background factors as indicators of experience variables. For practical reasons, many of these missing variables must remain unmeasured. Thus we must substitute a series of implicit or explicit assumptions about how these variables operate. But assumptions can either be made blindly for convenience or after one has carefully tried to identify the missing variables and think through their implications for the theory in question. The latter course is much more frustrating and disillusioning, but it is the surest way to make genuine progress in pinpointing inadequacies in existing theories and data.

In the sections that follow I shall discuss two very different though serious

problems that illustrate the complexity of the type of analysis that I believe is needed in the face of such missing information. These problems are: (1) the plethora of theoretical definitions of generic behaviors and their implications for measurement, and (2) the confounding of measured and unmeasured variables when individuals are aggregated in macrolevel analyses.

Both types of problems illustrate an important kind of temptation, namely that of substituting relatively simple operational indicators for theoretical constructs without paying careful attention to the underlying measurement model and required simplifying assumptions. In the case of behaviors, we note a tendency to define variables theoretically so as to facilitate generalizability at the expense of realism with respect to simplifying assumptions. In the case of aggregation by spatial criteria we encounter the need to specify unmeasured variables and mechanisms linking location in physical space to whatever dependent variable is being investigated.

The researcher, constrained by serious data limitations, usually finds it convenient to sidestep these issues. The theorist, trying to make sense of diverse empirical studies, is then confronted with an almost hopeless task and may be tempted to use the empirical information either selectively or anecdotally—or even to ignore it altogether.

THE MEASUREMENT AND CONCEPTUALIZATION OF BEHAVIORS

We have recently made considerable progress with respect to data *analysis* but relatively little with respect to data *collection*, and in particular our ability to observe, categorize, and measure behaviors. Even if one does not accept this assertion, I assume there is consensus on the need to improve our measurement of behaviors. There inevitably will be numerous practical obstacles to observing behaviors as they actually occur, but the problems I shall discuss are conceptual or theoretical and would occur even under the most ideal circumstances.

Human behaviors are extremely di-

verse, so much so that if we were to try to explain each one separately the situation would become hopeless. One way to resolve this problem would be to limit ourselves to a very restricted number of behaviors, but this is obviously not the course we are following. In a few instances behaviors pose no special measurement problems aside from observability. For the most part, these revolve around simple biological or economic needs. Certain other task-related activities are also rather directly linked to these basic needs, so that even though they may vary from culture to culture, they are easily classified.

Many behaviors of greatest interest to sociologists, however, are not of this nature and tend to be confounded in the real world. This is particularly true for behaviors that require a social partner or that are conditional on properties of a social system. We recognize that there are many different "forms" of these behaviors, which are often very different in terms of manifest or directly observable characteristics. Thus one may achieve status in a variety of ways, such as killing enemies, saving lives on the operating table, tackling opponents on a football field, or making vague political promises.

How do we get a theoretical handle on these diverse behaviors so as to group them into a much smaller number of conceptual ones? Although there are undoubtedly more, I am aware of four strategies, all of which rely on theoretical assumptions that usually remain implicit: (1) a linkage is assumed between the behavior and some motivational state, which usually appears in the theoretical definition; (2) there is an assumed causal linkage between the behavior and some consequence, which is an integral part of the definition; (3) the behavior is defined in terms of some general social standard with which it is compared; and (4) there is an assumed linkage between the behavior and other variables that cause this behavior to be repeated, with replication being an essential component of the definition.

Each of these definitional strategies thus requires simplifying assumptions that will be more or less realistic, depending

upon the complexity of the setting, the motivations of the actors, and the reactions of other actors who may also affect outcomes or ways in which behaviors are repeated. We should therefore not be surprised to find each definitional strategy being accompanied by certain theoretical biases that help the social scientist justify whatever simplifying assumptions are most convenient for that strategy. The more complex the behavior, the more crucial it is to uncover such biases and to state assumptions explicitly.

1. Behaviors Defined in Terms of Internal States

The lack of a perfect correspondence between attitudes and behaviors has been well documented. But it may not be so obvious that many general types of behaviors are *defined* in such a way that some internal state becomes an essential ingredient in the definition, so that measurement requires assumptions about these internal states. For instance, "aggression" may be defined as behavior intended to injure another party or "altruistic behavior" as any form of behavior intended to benefit someone other than the actor, without regard to the consequences for that actor. "Avoidance" may be defined as any behavior the purpose of which is to reduce contact with another actor, and "exploitation" may be conceived as the use of another actor for one's own ends.

What simplifications seem necessary in using this definitional strategy? Let us illustrate with the aggression example. If there were a closed set of behaviors that could be listed, each of which is clearly linked to the injury of another party, one could supply the observer with the names of these familiar behaviors. Two kinds of difficulties are encountered, however. First and most important, many behaviors serve several ends at once. In fact human beings are remarkably adept at creating situations in which actors can kill several birds with one stone. Aggression may be instrumental in weakening the competitive position of an opponent or in attaining status among one's peers. This means that the same behaviors can be classified in

different ways if the theoretical definition is stated in terms of a postulated internal state. Thus several different types of behaviors may be hopelessly confounded. One theorist may refer to aggression, a second to exploitation, and a third to competitive behavior, all "observed" in the same way.

The second obvious problem is that the relationships between the internal state and the behavior may be more or less direct, may involve differing time delays, and may be subject to distortion by either the actor or the observer, whose theories of social causation may differ. Some forms of aggression are very overt, immediate, and nonsubtle. Others are very delayed, so much so that the observer may not be around at the time they are enacted. Still others may be subtle and disguised as behaviors of a different type. In yet other instances, the actor may intend to injure another party but may fail because he or she does not adequately understand the motivation of that party. The observer, too, may misread the intent of the first actor.

Given these difficulties, what kinds of simplifications are we tempted to make? First, we may confine ourselves to simple laboratory settings in which actors' choices are restricted to a small number of alternatives, each of which is assumed simply linked to a postulated internal state. Aggression, altruism, or avoidance thereby may be identified with relatively simple operations such as that of pushing a blue rather than a red button. The measurement-conceptualization problem is then transformed into one of assessing "external validity" or generalizability.

A second simplifying strategy uses a restricted subset of behaviors most simply linked to the internal state referred to in the conceptual definition. If some forms of aggression are subtle, indirect, or delayed, these are excluded from the operational definition because they are difficult to interpret. The result is a nonrandom selection of behaviors biasing the findings in unknown ways. If educated persons are more likely to use subtle forms of aggression than less educated ones, then aggression among the former group will be underestimated.

A third strategy is closely linked with the second. One may limit oneself to a small number of "master motives" that underlie nearly all human behaviors, so that whenever a behavioral form can be located that supports one's theory, this master motive is invoked in labeling the behavior to confirm this theory. Thus if one believes that an intent to injure others is present in almost all human interactions, then nearly every form of behavior can be considered as a subtle form of aggression. Similarly, it is possible to infer an exploitative motive behind almost every behavior. Those who see status-seeking as a prime motivator may define whatever behaviors they see as instances of status-seeking, and to some degree they will probably be correct. Since most behaviors in complex settings involve mixtures of motivations, there is a wide-open opportunity to label any given behavior as an instance of many different kinds of generic behaviors defined theoretically in this fashion.

A fourth way to simplify the classification of behaviors is to accept the actor's word for his or her own motivation. Rarely are we so naive as to believe a respondent who claims a pure motive, but in effect this may be what actually occurs whenever we ask a respondent or witness to recall what has taken place. To do so, one must rely on popular vocabulary and common definitions, rather than scientific usage. This may result, to an unknown degree, in a generalization process involving the substitution of inferred generic terms for "directly observed" behaviors (such as a blow or spatial movement). The social scientist wishing to give precision to behavioral concepts that have popular meanings is thus faced with a dilemma. Either one must rely on popular definitions when events are being reported, or one must develop a more precise terminology that does not correspond to this popular usage. Whenever one wishes to generalize across cultures or languages, these problems become even more serious.

A fifth temptation is to use clues based on past behaviors to infer motivation. For instance, if an employer has not recently hired a sufficient number of blacks and

then claims that current efforts are sincere, though unsuccessful, it may be inferred that this employer is discriminating against blacks (defined in terms of differential treatment *because of* race) if the ratio of black to white hirings does not reach some predetermined level. It may be, of course, that the past record also was a resultant of forces beyond the employer's control. The point is that intent is inferred on the basis of past practice or results, but without an explicit theory allowing for alternative explanations.

Whenever one wants a measure of the intensity of a behavior, we may add a sixth temptation to the list. This is to use an objective measure of the behavioral intensity or duration, without partitioning this among the several underlying motivations. For instance, suppose the intent to injure another person is only a very minor component of the actor's motivation. Perhaps self-defense or a desire to reduce competition is the major goal. Degree of aggression may be measured solely in terms of the behavioral act, thus bypassing the problem of measuring motivational strength (or utility) independently of the behavior itself. This may then affect one's theoretical interpretations. Suppose, for example, that the decimation of American Indians by white settlers was primarily based on the utilitarian goals of securing more land or protecting one's family. It would then be misleading to build an explanatory model, representing these actions as extreme aggression. The major point is that the relative importance of different underlying motivations needs to be kept distinct from that of the frequencies and intensities of behaviors unless it can be assumed that behaviors and motivations can be linked in a simple one-to-one fashion.

2. Behaviors Defined in Terms of Consequences

One may sidestep the problem of identifying and measuring internal states by focusing entirely on the consequences of the behaviors. Our discussion of this alternative strategy can be more brief since the issues once more illustrate our main point that there are numerous theoretical

assumptions needed to carry out this kind of measurement strategy whenever the social situation is at all complex. First, *someone* must assess the consequences since a causal theory is being invoked to link the behaviors with some set of outcomes. But whose theory? The actor's? Other parties' in the situation? The supposedly neutral observer's? And which outcomes and using what time span? If there are both short-term and long-term consequences that are not identical, which should be used? And what if these outcomes are conditional on the behaviors of *other* actors in the social setting?

Once more, there will be pressures to simplify. One possibility is to confine oneself to very simple situations. Another is to dichotomize consequences as either occurring or not, thereby ignoring variations in degree. Still another is to ignore multiple consequences and look only at those consequences that are obvious and immediate in a temporal sense. Taking the example of aggression (now defined as behavior that results in injury), this would rule out many forms of delayed aggression or subtle types where the consequences seemed to be highly indirect. Again, this will result in biased measures to the degree that not all actors employ the same forms of aggression.

Whenever the consequences are conditional on the responses of other actors it will be especially tempting to simplify one's causal theory to obtain an unambiguous measure of the behavior. Suppose one defines discrimination as behavior that results in unequal consequences for classes of actors defined in certain ways, as for example by age, sex, or race. Suppose an employer makes a set of judgments that results in the hiring of disproportionately few blacks. Was the lack of hiring solely a consequence of the employer's action or also of the behaviors of the applicants for the position? It is tempting to try to get off the hook by crudely matching blacks and whites on "relevant" variables, as defined by the investigator, usually in accord with data availability considerations.

Furthermore, if the discriminatory behavior leads to some sort of response that jointly affects the outcome, then how does

one define or measure the behavior without taking this response into consideration? How does one measure teaching effectiveness or leadership quality? The most tempting resolution is to assume away the problem by taking the second actor's behavior either as being totally dependent on that of the first or as having negligible consequences in its own right. Thus we often assume that minorities, children, and other relatively powerless actors are totally powerless, so that their own responses can be ignored.

Basically, this measurement strategy may tempt one to ignore all sorts of intervening and conditioning variables by grossly oversimplifying the causal connection between the behavior in question and the consequences that are being identified. There will be a vested interest in simplifying this set of consequences, just as the prior strategy creates one in simplifying the actor's motivational structure.

3. *Behaviors Defined in Terms of Standards*

Certain kinds of behavior are defined theoretically in terms of some social standard, which is often either rather vague or differently defined by actors having contrasting interests. For example, deviance is defined in terms of departures from social norms, which may be subject to dispute. In the case of criminal behavior the norms may be clearly stated in the form of laws that are enforced by official sanctions, but the laws themselves may vary from one jurisdiction to the next. Similarly, the notion of exploitation in an exchange relationship may be defined in terms of some standard by which equity can be evaluated. There are also a number of popular terms such as "mentally disturbed," "addiction," or "antisocial" behavior that presumably imply some sort of implicit standard.

In all of these instances an investigator who attempts to measure the degree of departure from such standards is faced with a dilemma. If reality is fuzzy, how is it possible to obtain precise measures? We have, it seems, a kind of sociological Uncertainty Principle that places an upper limit on the accuracy of measurement of

such behaviors. How can one measure degree of conformity to imprecise norms? What if actors define a "fair" rate of exchange differently? Is there any meaning to a notion such as exploitation? The terms "conformity" and "exploitation" can be used in ideological writings, but can they become a legitimate part of a scientific vocabulary?

I believe it is possible to retain the essential features of the theoretical arguments that use such concepts, provided we make careful distinctions and somehow build the degree of fuzziness into these theories, as a separate variable. Whenever there is dissensus on group norms or on what constitutes a fair rate of exchange, this in itself becomes a datum of relevance to actors. Perhaps a measure such as a standard deviation can be used as a measure of such dissensus whenever the issue is unidimensional. When it is not, this in itself requires analysis because it will constitute an additional source of fuzziness for the actors concerned. Where the standards for a given subgroup are clear-cut but distinct from those of another, two separate variables can be delineated, as for example degrees of deviance from Group A norms and from Group B norms.

The temptation, here, is to substitute more precise standards for the true but fuzzy ones. One way to simplify the situation is to substitute some measure of average behavior for the norm, thereby giving it a definite meaning, although one that may differ from its meaning to the actors themselves. As is well known, there are two meanings to the word "normal," namely some measure of central tendency, on the one hand, and some idealized value, on the other. Insofar as these may differ according to the situation, our theories will then need to make the necessary distinction between the two types of standards.

Another alternative is to confine our operational measures to absolute values, using zero as the comparison point. Thus one may take suicide rates as a measure of deviance, but only if all suicides are socially defined as contrary to normative expectations. If certain suicides are not defined in this fashion, however, and if

normative standards vary across the units being compared, then clearly suicide rates will not be an appropriate indicator of deviance. Unfortunately, many of our theories of deviance are not very precise as to the standard about which deviance is to be measured or whether the norm is to be defined in terms of a measure of central tendency or some legal or ethical standard.

4. Behaviors Defined in Terms of Replications

The fourth strategy, that of relying on replications, seems most common among behavioral psychologists and social psychologists who rely heavily on experimental designs involving repeated measurements. Given very simple settings and assumptions about motivating factors, such a strategy indeed makes sense. In generalizing beyond the laboratory setting, one obviously cannot rely so heavily on operational definitions of behaviors that require such replications. For example, if one defines reinforcing behaviors as those that are followed by later instances of the behaviors they are supposed to reinforce, one must rule out other causes of the replicated behaviors. Perhaps the behaviors are repeated because they are constrained or influenced by factors unknown to the investigator.

The more general point is that whenever several variables jointly affect a behavior, a reliance on the replication operation to measure a behavior will lead to both theoretical ambiguities and also empirical irregularities that make measurement much more difficult. In short, the research operations cannot be generalized readily to more complex situations in which replications occur under much less controlled circumstances. In making comparisons across such situations, both the measurement operations and the situations themselves will vary, so that theory and measurement become hopelessly confounded.

Whenever manifestly similar behaviors are rarely repeated in real-life situations we are faced with another kind of dilemma, the resolution of which will require theoretical assumptions. The observation period, being arbitrary in most in-

stances, may in part determine the relative frequency of occurrences within a given population. If this proportion is very small, one will be confronted with a highly skewed response variable. This may be countered by defining the behavior in question as merely an instance of a larger class of behaviors that occur more frequently, but then problems of aggregation and homogeneity will arise. That is, the diverse behaviors that have been lumped together into the class may have different sets of causes or consequences.

Another alternative is to aggregate over individuals assumed to be similar in certain respects, so that one then works with behavior rates as estimates of probabilities of engaging in the behavior. Obviously this requires a well-defined theory as well as data sufficient to classify such individuals into categories that are homogeneous with respect to the parameters of the equations and not merely a set of "objective" attributes of individuals, such as age, sex, or SES. Often these aggregating decisions are made on the basis of convenience or convention, with the theoretical rationale being only implicit.

Finally, one may lengthen the time span so that behavioral acts of a given type will be more frequent. But this not only causes inconvenience for the observer but also is likely to introduce heterogeneity into the situation. The individual's motivation may have changed, the method of data collection or observational procedure may have to be modified, and situational factors may also be changing. The relative gains and costs of these alternative resolutions will of course have to be assessed for each particular case, and this will require a number of untested theoretical assumptions.

To conclude this section on behaviors, in considering the implications of each of these definitional strategies the essential point is not that assumptions can or should be avoided but that they need to be made explicit. Furthermore, we see that each measurement strategy requires the use of theoretical assumptions, only some of which can be tested. Our own experience (Blalock and Wilken, 1979) in attempting to analyze selected basic concepts in the field of intergroup relations is

that an apparently simple form of behavior, such as discrimination, aggression, or avoidance, requires for adequate conceptualization auxiliary measurement theories containing as many as twenty or thirty variables. I would be surprised if the same does not hold for other reasonably general social behaviors. It is no wonder, then, that our rate of progress in conceptualizing and measuring these behaviors has been slow and uneven.

THE CONFOUNDING OF VARIABLES IN AGGREGATING BY GEOGRAPHIC PROXIMITY

The literature on aggregation and disaggregation is both technical and discouraging in its implications, if one takes seriously the goal of integrating microlevel analyses, based on the individual as unit of analysis, with macrolevel studies where groups are the focus of concern.¹ Ideally, theories on the one level should be consistent, in some sense, with those on the other (Hannan, 1971:18-23). Furthermore, since some groups are nested within larger ones, and since in many instances group boundaries are fuzzy and therefore arbitrarily defined, it is also desirable to pass systematically from one aggregate level to another, as for example from counties to states.

In discussions of aggregation in the econometrics literature it is assumed that those who do the aggregating have a theoretical rationale for grouping individuals into behaviorally homogeneous aggregates. In most instances where sociologists use aggregated data, however, the grouping operation has already been done, usually with another purpose in mind. In these instances aggregation can hopelessly complicate one's analysis unless the criterion for aggregation can be fitted rather simply into one's theory. For instance whenever we are dealing with a corporate group as a unit of analysis it

¹ For three very different, though complementary perspectives on the aggregation problem, the reader is referred to the works of Firebaugh (1978; 1979); Hannan (1971) and Hannan and Burstein (1974); and Irwin and Lichtman (1976); and Langbein and Lichtman (1978). These sources also contain numerous additional references.

makes good sense to aggregate over individual members to obtain measures of group properties. Presumably, our interest will center on this group and other comparable groups as actors, as for example whenever business firms produce tangible products or state legislatures enact laws or allocate budgets.

In many other situations the picture is not this simple, however. Sometimes we may aggregate over a territorial unit that for certain purposes may be considered a corporate group (e.g., a state or county), but where the corporateness may not be an essential feature of the theory in question. For example, we may be studying crime rates in various counties, where county-level policies have virtually no impact upon these rates. Or we may have segregation indices based on block data that are available only for a central city, whereas the SMSA extends far beyond these arbitrary political boundaries. Or our theoretical interest may be on the microlevel, say, in understanding why individuals commit suicide or tend to avoid members of another group. Yet the data may be available only in aggregated form, as for example census tract data. In no sense can these territorial units be said to constitute true groups, nor is there any pretense that we are interested in highly coordinated behaviors.

In such instances we use the aggregated data because they are the only ones available. What can we say about the problems created when individuals are aggregated by spatial criteria? The answer depends upon the causal connections between the criteria used in grouping and the variables that appear in our theories (Blalock, 1964; Hannan, 1971).

The usual assumption is that the aggregation criterion, which we shall call A , is an independent variable in the model and that it is not operating to confound the effects of the independent variables under study. When we acknowledge the myriad ways in which spatial location may be linked to the variables of interest to sociologists we can anticipate the complications that such aggregation may produce. People are influenced not only by what goes on around them in the immediate present, but also in the past. They may

have moved from one community to another, carrying with them those effects in the former residence that we refer to as "background influences." Furthermore, not all individuals are affected in the same ways by the variables in their immediate environment. Some may have lived in the area all their lives. Others may have moved into the area because of its local traditions, whereas others may have entered and resisted them.

To come to grips with the problems that such complexities create, it will be helpful to examine several models that are themselves oversimplifications of the actual processes at work. We begin with a model in which it is presumed that the territorial units are closed to migration and that contextual effects operate entirely within the boundaries that have been operationally defined.

A Closed-System Example

Suppose we are willing to assume that our criterion for aggregation, here a spatial one, operates only as an independent variable. Of course we do not imagine that location, *per se*, affects the variables of interest. Instead, one's spatial position may be taken as a cause indicator of the unmeasured variables that are presumed to be the true causes of the variables in question. Take the model of Figure 1 as an illustration. Perhaps X_1 represents educational achievement, assumed to be a constant property of the individual once the process has been completed. Suppose X_2 represents a relatively constant type of personal value (say, egalitarianism) that has been developed over time as a result of socialization experiences linked closely

Figure 1.

with one's spatial location. Let X_3 represent another kind of attitudinal variable (say, one's attitude toward a specific minority) that is readily modifiable and therefore subject to changes in one's immediate environment. Finally, suppose X_4 represents a contextual variable (such as a set of sanctions) that operates in the immediate locale.

Now suppose that all these X_i affect a certain form of behavior Y . To simplify we shall assume that the effects are additive, so that the behavior Y may be represented by the equation

$$Y = \alpha + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \epsilon \quad (1)$$

In the model of Figure 1 we have drawn causal arrows from A to each of the X_i representing the argument that one's location in space in part determines the levels of these X_i as intervening variables.

In any realistic situation an investigator will be unaware of or unable to measure many of the X_i that affect Y . Suppose, for example, that only X_1 and X_4 have been measured and used in an incorrectly specified equation for Y . The least-squares estimates b_1 and b_4 of the parameters β_1 and β_4 will then be biased to the degree that the omitted intervening variables are correlated with X_1 and X_4 . In the model of Figure 1 the intercorrelations among the X_i are due solely to A , implying that a control for A (if perfectly measured) would wipe out these interrelationships. Thus if we were to examine the data *within* a single territorial unit, we would find no association among the X_i , implying that even in the incorrectly specified equation

$$Y = a + b_1 X_1 + b_4 X_4 + e \quad (2)$$

the estimates b_1 and b_4 would be unbiased estimates of β_1 and β_4 .

Of course this is a highly oversimplified model in which there are no other arrows connecting the X_i , whereas in actuality we would expect intercorrelations within each area. But this prototype model is presumably illustrative of more complex ones and involves the kind of assumption needed to justify controlling for residential

area. The essential notion is that many causal factors are generally confounded together because of common residence. Therefore, a control for residence is expected to weaken these associations, if not do away with them altogether.

What is less obvious is that when we aggregate by location we do the very opposite of controlling for A . In grouping by A we put together people who are similar in their X_1 levels. But they will also be similar with respect to their X_2 , X_3 , and X_4 values. Suppose the X_i are labeled so that the relationships with A are all in the same direction, so that we may represent them by positive signs. Then persons who reside in a location where the X_i values tend to be high will also have high X_2 , X_3 , and X_4 values. If we shift our analysis to the macrolevel, using the estimating equation

$$\bar{Y} = a^* + b_1^* \bar{X}_1 + b_2^* \bar{X}_2 + b_3^* \bar{X}_3 + b_4^* \bar{X}_4 + e^* \quad (3)$$

where the \bar{X}_i represent mean values for the same X_i as represented in Figure 1, we may ask how the new least-squares estimates b_i^* may be expected to compare with estimates that would have been computed on the basis of individual-level data.

What happens in this case is that the \bar{X}_i will be more highly intercorrelated than the microlevel counterparts X_i . If we have specified the model perfectly and if there is absolutely no measurement error in any variable, this will not lead to any systematic biases in the macrolevel estimates of the parameters. But because of the increased intercorrelations we encounter a multicollinearity problem that tends to increase sampling errors.

It is more important, however, to consider the implications of this confounding of intervening variables in instances where there are specification errors. Suppose we do not know all the X_i that cause Y and that are intercorrelated because of location. To be specific, suppose we have included only \bar{X}_1 and \bar{X}_4 in the equation for \bar{Y} . Our biases in parameter estimates will now be much more serious than in the micromodel discussed earlier. In effect, if we shift to group means but ignore certain of the causes of \bar{Y} , the effects of these omitted variables are even more con-

Figure 2.

founded with those of the intervening variables we have been able to include. Put another way, our aggregated model is more sensitive to at least these types of specification errors than is the micromodel, even where the location variable A has been ignored.²

For the model of Figure 1 we thus have three analysis possibilities. Our best option is to use microdata and to control for A . Our second best bet is to use microdata and to ignore A . In doing so, if we happen to leave out any of the intervening X 's we will confound their effects with the remaining X 's. The third option is to obtain between-area data by aggregating, in which case we increase the intercorrelations among the intervening variables, thereby confounding to an even greater degree the effects of the omitted X 's with the causal variables in which we are explicitly interested.

We cannot say that aggregation will always have this effect, but to the degree that reality approximates the model of Figure 1 this will hold. In the extreme case where we have measured only X_1 , the original model could be replaced by Figure 2 in which the arrow from A to Y has been drawn as direct. Here A is creating a partly spurious relationship between X_1 and Y , and should be controlled. But if we aggregate by A we are grouping by a cause of Y , and as I have shown elsewhere (Blalock, 1964) this produces a systematic bias in our slope estimate linking X_1 and Y ,

² Irwin and Lichtman (1976) stress that the essential criterion in deciding between a micro- and a macromodel is the relative degree of specification errors involved. Here, this criterion implies that the micromodel is to be preferred.

Figure 3.

a bias that may be interpreted as resulting from the confounding with X_1 of all other effects of A that are also causes of Y .³

An Open-System Example

Now consider the somewhat more complicated but also more realistic situation in which persons are immigrating into and emigrating from each of the areal units. Here we must take A as a dependent as well as an independent variable. Of course the area is not "dependent" upon its residents. What we mean is that since our microunits of analysis are individuals or families, the particular area in which they are located is dependent upon their decisions. To study this kind of situation we now must bring in the time dimension and try to distinguish between contemporary and past influences, as well as internal states that we are willing to assume are stable over time as contrasted with those that may change as a result of immediate stimuli.

Consider the model of Figure 3. Here we distinguish between an individual's location at time 1, namely A_{t1} , and his or her location at time 2. Migration may or may

³ Firebaugh (1978) discusses this kind of situation in terms of a general criterion for avoiding aggregation bias, namely that the association between Y and \bar{X} , controlling for \bar{X} , must be zero if bias is to be avoided. In other words, \bar{X} must not belong in the equation for Y , a criterion that will not be satisfied if \bar{X} is a surrogate for other variables that have been omitted from the equation because of specification errors.

not have occurred in the interim. Following Stinchcombe's (1968) discussion of historical explanations we may draw an arrow linking A_{t1} to A_{t2} . What one does today, or where one is, influences tomorrow's behavior or location, if only in the sense that once a given pattern of behavior has been learned there is a vested interest in not changing it unless there are specific pressures to do so. For those who have not migrated, A_{t1} and A_{t2} will be identical. The degree of association between these two variables will depend on the proportion of migrants and, although not indicated in the diagram, this proportion itself could be one of the contextual variables that affect behavior Y , perhaps through the sanction system represented by X_4 .

Suppose X_1 and X_2 represent variables that do not change over time. Therefore the change in location has not affected either of these variables. I have represented this by drawing in double lines without arrowheads to indicate that X_1 and X_2 remain identical at the two points in time. Suppose, however, that X_3 and X_4 may be affected by the new location as well as the old. Therefore I have drawn arrows to X_{3t2} from both X_{3t1} and A_{t2} (and similarly for X_{4t2}), making the assumption that the changes produced by the change in location are almost immediate. Finally, the behavior Y at time 2 is taken as dependent upon the contemporary values of the X_i , as was also true in Figure 1.

Now suppose both migrants and non-migrants are lumped together, as is often the case in microlevel analyses and as is practically always necessary for aggregated data. Again, if we have perfect measures of the contemporary values of all the X_i , we may estimate their separate effects without bias, though if they are too highly intercorrelated we shall have large sampling errors. But suppose there are specification errors, either in the form of poor measurement of some of the X_i or their omission from the equation. Previously we noted in Figure 1 that a control for A would remove all the intercorrelations among the X_i , so that if some were inadvertently omitted the estimates of the structural parameters for the others would

remain unbiased. This will not be true, however, for the more complex model of Figure 3 unless both A_{t1} and A_{t2} are simultaneously controlled. If we looked only within A_{t2} we would expect to find a correlation between X_1 and X_2 that would be some function of the proportion of immigrants, since these variables depend only on the factors operating during the earlier period. Presumably, X_1 's correlation with X_3 and X_4 would be somewhat weaker, owing to the contemporary factors affecting the latter two variables. The correlation between X_{3t2} and X_{4t2} , assuming we are dealing with within-area data, will depend on the relative importance of contemporary influences as compared with earlier ones.

What happens when we aggregate using only the present location A_{t2} ? Once again, we do the very opposite of controlling for location and thereby tend to confound the effects of the four X_i . But we now also are grouping by a variable that may be dependent upon certain of the X_i . In Figure 3 I have drawn arrows from X_{1t1} (say, education) and X_{3t1} (say, attitude toward a minority) to A_{t2} , presuming that these two X_i have influenced the decision to migrate. But if we aggregate by A (at time 2) we are manipulating a dependent variable in terms of the relationship between X_1 and X_3 , and this will distort their relationship in an unknown way.

The models with which we have been concerned are grossly oversimplified and merely illustrative of the problems one encounters when aggregation operations are poorly understood. In a sense, aggregation by spatial units is understood in that the criteria for aggregation are clearly operationalized. But what we generally lack is a theoretical model connecting spatial location with the other variables in the system. Thus we achieve operational simplicity at the expense of theoretical clarity. The result is that we are unable to link our macrolevel aggregated data with the microlevel causal processes that may have produced these data. Put another way, if we wanted to insert the aggregation criterion into the causal model we would find that the model would have to be highly complex because one's spatial

location is not simply related to the other variables in these models.

CONCLUDING REMARKS

These are but two among many possible illustrations of the need for careful conceptualization and attention to measurement problems and of the fact that theoretical and methodological issues are closely interconnected. They also suggest the importance of bringing implicit assumptions out into the open, even where the added variables in the model may have to remain unmeasured in any given piece of research. Unless this is done, many of these variables will remain confounded with measured variables. It will then be difficult to decide rationally as to the relative merits of alternative design strategies needed to unravel their interrelationships.

In particular, it is important to reemphasize how crucial it is to avoid the temptation to sidestep theoretical and conceptual issues by resorting to very simple operational procedures. I have illustrated this in terms of aggregation according to spatial criteria. A similar temptation also arises with time. Certain variables, such as education, experience, or investments, may be indirectly measured in terms of lapsed time, whereas the conceptual variables of real interest may be only very loosely defined theoretically. The literature on the age-period-cohort problem, for example, relies almost exclusively on calendar dates and lapsed time, as indicators of experience variables, as for example the assumed common experiences of persons born during a five-year period. Relatively sophisticated methodological techniques may be used to attempt to disentangle the separate effects of functionally interrelated variables, as operationally defined. But the true cohort or period effects remain only vaguely specified, as does the linkage between chronological age and maturation. Obviously, sophisticated data analysis techniques, alone, cannot resolve these and other problems unless the theoretical and measurement-error models are clearly specified (Glenn, 1976).

Initial efforts to specify models more completely and to theorize explicitly about linkages between measured and unmeasured variables are almost certain to have discouraging implications. We shall realize how many missing variables and hidden assumptions tend to be ignored in empirical data analyses, as well as theoretical interpretations of empirical results. This obviously carries with it the danger of inhibiting further work and encouraging a hypercritical appraisal of the sociological literature. I believe this is a risk we must take, however, if we are to create a really cumulative knowledge base.

This, in turn, leads me to one inescapable conclusion. Sociologists need to work *together* on these problems. We can ill afford to go off in our own directions, continuing to proliferate fields of specialization, changing our vocabulary whenever we see fit, or merely hoping that somehow or other the products of miscellaneous studies will add up. The plea, then, is for a sustained effort to clarify our theoretical constructs and self-consciously to ask ourselves how different strategies of conceptualization relate to problems of data collection and measurement.

There will still be plenty of room for differences in terms of the kinds of propositions we wish to state and test, the assumptions we are willing to make, the problems we study, the courses of action we recommend, and the theoretical and ideological biases with which we operate. In the proposed joint effort, there is a need for many different kinds of skills, interests, and knowledge bases to help solve technical issues, bring out implicit assumptions, and try to reach a working consensus on our conceptual apparatus and epistemic correlations.

If nothing else, such a concerted effort will better enable us to comprehend what each of us is trying to say and to appreciate more fully the complexity of the theories and analyses needed to understand a very complex reality. If we do not make this concerted effort, I fear that sociology in the year 2000 will be no more advanced than it is today, though perhaps

it will contain far more specializations, theoretical schools, methodological cults, and interest groups than, even today, we can readily imagine.

MANUSCRIPTS FOR THE ASA ROSE SOCIOLOGY SERIES

Manuscripts (100 to 300 typed pages) are solicited for publication in the *ASA Arnold and Caroline Rose Monograph Series*. The Series welcomes a variety of types of sociological work—qualitative or quantitative empirical studies, and theoretical or methodological treatises. An author should submit three copies of a manuscript for consideration to the Series Editor, Professor Robin M. Williams, Jr., Department of Sociology, Cornell University, Ithaca, New York 14853.

THE CONTRADICTION OF DOMINATION AND PRODUCTION IN BUREAUCRACY: THE CONTRIBUTION OF ORGANIZATIONAL EFFICIENCY TO THE DECLINE OF THE ROMAN EMPIRE*

ROBERT J. ANTONIO

University of Kansas

American Sociological Review 1979, Vol. 44 (December):895-912

One of the contributions of Max Weber is his distinction between formal and substantive rationality. When viewed in relation to his theory of bureaucracy this distinction provides a context for clarifying the domination aspects from the productive activities of organization. The case study of Roman bureaucracy is used to illustrate how the contradictions between two coexisting forms of rationality—one reflecting the control of persons and resources and the other the production (and distribution) of goods and services—contributed to the decline and collapse of the Roman Empire.

Max Weber stressed the "specific and peculiar rationalism of western culture" (Weber, 1958:26). Furthermore, he was seriously concerned about its continuing intensification and diffusion through a related set of ever advancing developmental processes involving the disenchantment of nature, the scientization of thought, the deepening penetration of advanced technology into practical activities and the bureaucratization of social life. Weber's discussion of western rationalization¹

does not posit movement toward a Hegelian rational society where truth is actualized in social relations. Instead, Weber limits his emphasis to advances in the spheres of rational calculation and exact coordination of collective action. This refers to increased technical efficiency in controlling both the material and human environments. For Weber, these were by no means utopian developments because the consequent advances in production were accompanied by new forms of domination, alienation and waste.

Weber (1968:85)² distinguishes between

I am indebted to Michael Lacy for his careful reading and editorial, organizational and substantive criticism of several drafts of this paper. Also, David Willer has provided much insightful criticism and encouragement; he has significantly contributed to the work. Furthermore, thanks go to Scott McNall, George Ritzer, Alan Sica, Norm Yetman, and Augustus diZerega for useful comments and suggestions at various stages of the research. Finally, two anonymous *A.S.R.* reviewers provided solid criticism that contributed to the final draft. All these individuals have helped shape this essay, but I am alone responsible for any errors. This investigation was supported by University of Kansas research allocation #3485-x0-0038.

¹ Rationalization must be understood in relation to Weber's broader concept of reason. The term is most often associated with social action and structures emphasizing demystification, exact calculation, prediction and quantification concerning the *means* of action. This meaning is reflected in Weber's use of "instrumentally rational action" (1968:71-4), "technical rationality" (1968:63-8), "rational economic action" (1968:71-4) and "formal rationality" (1968:851-6). Weber contrasts this to "value-rational action" (1968:24-6 and "substantive ration-

ality" (1968:85-6) which involve reflection about ultimate ends. Weber's concept of rationalization refers to (see Gerth and Mills, 1958:51) the "disenchantment" of the world—the displacement of "magical elements of thought" by ideas which "gain in systematic coherence and naturalistic consistency." In other words, this means the growing dominance of formal reason. Horkheimer (1974:vii) captures the sense of this process: "'Reason' for a long period meant the activity of understanding and assimilating the eternal ideas which were to function as goals for men. Today it is not only the business but the essential work of reason to find means for goals one adopts at any time." Rationalization should be interpreted, in the broader sense, as the intensification of means-oriented reason in social and technical organization as well as action/thought.

² Here and throughout much of the paper, I am quoting from Weber's *Wirtschaft und Gesellschaft* (*Economy and Society* [1968]) edited in English by Roth and Wittich. This work is appropriate because it involves "Weber's major comparative treatment of forms of domination" (Roth, 1965:213). In this work *Herrschaft* is translated as domination. It means the situation in which the manifested will (*command*) of the ruler or rulers is meant to influence the conduct of one or more others (*the ruled*) and actually does influence it in such a way that their

the " 'formal rationality [my emphasis] of economic action' . . . used to designate the extent of quantitative calculation or accounting which is technically possible and which is actually applied" and *substantive rationality* involving "the degree to which the provisioning of given groups of persons . . . with goods is shaped by economically oriented social action under some criterion (past, present or potential) of ultimate values (*wertende Postulate*), regardless of the nature of these ends." Weber recognizes explicitly that the two types of reason are often contradictory. For example, he (1968:138) states that "the maximum of *formal* rationality in capital accounting is possible only where workers are subjected to domination by entrepreneurs." Weber asserts that this "is a further specific element of *substantive* irrationality in the modern economic order."

The contradiction of formal and substantive rationality is also evident in Weber's concept of bureaucracy. As he defines it, bureaucracy manifests extreme formal rationality. The core of the Weberian conception is the "master's" control of a hierarchy of officials coordinated through rational discipline. Weber (1968:1149) defined discipline as "nothing

but the consistently rationalized, methodically prepared and exact execution of the received order." His concept of bureaucracy includes many important characteristics: e.g., the existence of official jurisdictional areas, management based on written files, formal training, official activity demanding full working capacity, monetary wages and impersonal rules. Nevertheless, discipline and hierarchical power relations are the central and integrating attributes. Weber (1968:1149) asserts that bureaucracy is discipline's "most rational offspring." For this reason it "is technically the most highly developed power instrument in the hands of its controller" (Weber, 1968:991). Thus, Weber (1968:954) is able to claim, "*Rationally regulated* association within a structure of domination finds its typical expression in *Bureaucracy*."

Throughout his analysis of bureaucracy Weber emphasizes "compliance," "obedience," "rule" and "authoritarian power of command" (see Weber, 1968:212-26; 941-1005). For Weber (1968:975) bureaucracy means the "discharge of business according to *calculable rules* and 'without regard for persons.'" Its so-called technical superiority evolves from this disciplined "objective" activity which makes possible the efficient coordination of collective action. Bureaucratic discipline is similar in form to capital accounting in that both stress exclusively maximizing the calculability of means through the standardization of action.³ Both activities seek to exclude all matters extraneous to the specific relevant instrumental concerns. Weber (1968:975) asserts that bureaucracy advances "the more it is 'dehumanized,' the more completely it succeeds in eliminating from official business love, hatred, and all purely personal, irrational, and emotional elements which escape calculation." This list should be extended to include value-rational³ activities that are not part of the instrumental task, because these too are "human" actions that potentially threaten "official business."

As a structure of domination, Weberian bureaucracy is organized to achieve the

conduct to a socially relevant degree occurs as if the ruled had made the content of the command the maxim of their conduct for its very own sake. Looked upon from the other end, this situation will be called *obedience*. (Weber, 1968:946)

The English interpretation of *Herrschaft* has been the topic of controversy in recent years. Parsons (1960a:752) believes that "in its most general meaning" the term should be translated as "leadership" or "authority," not domination. The reader should see Roth and Wittich (Weber, 1968:61-2n), Eendix (1977:481-2), Cohen et al. (1975a; 1975b), Parsons (1960a; 1960b:149-55; 1964:58-60; 1972; 1975), Bruun (1972:287-8) and Hättich (1967). I concur with Cohen et al. (1975a:236-9) that Parsons overemphasizes the normative aspects of Weberian theory and leaves coercion underdeveloped. Furthermore, as I (Antonio, 1979) have shown in another paper, Parsons criticizes Weber for overemphasizing coercion and for adhering to a "zero-sum" (coercive) concept of power. Yet elsewhere he rejects interpreting *Herrschaft* as domination because it emphasizes coercion "rather than the integration of the collectivity, in the interest of effective functioning" (Parsons, 1960a:752). Thus, there are apparent inconsistencies in Parsons's own reading of Weber that could be construed to support the non-Parsonian interpretation of *Herrschaft*.

³ See fn. 1.

commands of those who control it. The occupants of the structure's various offices are expected to comply with the formally rational expectations of their roles. On the other hand, they are excluded from participation in substantive decisions and are often not even privy to information about them. Such policy defining activities are the exclusive prerogative of the masters.

Weber (1968:989) suggests that bureaucratic social structure is often accompanied by a "crypto-plutocratic distribution of power" in the broader social order. In such cases the bureaucracy is almost always a means for realizing the interests of a ruling elite. Thus, as in the capital accounting of the economic sphere, the highest level of formal rationality in bureaucracy is often substantively irrational. That is, when bureaucracies are instruments of elite domination, as they historically often have been, successful completion of formally rational routines involve expropriation, directly contradicting substantive rationality. In other words, the more efficient the bureaucracy in completing these routines, the more able the ruling elite is to maximize its control while minimizing its provisioning of the population.

When it is analyzed as a structure of domination, bureaucracy's corruption, waste, red tape and inefficiency in one context can be related logically as well as empirically to its speed, precision and efficiency in another. Weber believed that the master, on the basis of his/her control of the material means of management, dictates the organizational goals that shape production rationality. Furthermore, he (1968:992) argued that "administrative secrecy" and selective misinformation excludes the public from accurate knowledge of these goals. The official ideology of bureaucracy proclaims its production of necessary goods and services, while its operative goals almost always involve the maximization of power over people for the extraction, accumulation and control of resources. This situation requires the analyst of bureaucracy to consider two forms of organizational rationality—one reflecting production (and distribution) and the other the logic

of domination. The strength of Weber's approach is that it provides a context through which the relations of both modes of rationality are considered.

Extreme formal rationality and exact calculation in the service of bureaucratic ends may be irrational from the perspective of broader societal values and interests. For this reason, the understanding of bureaucracy as a structure of domination bears little relation to its official service goals, to the maintenance of social well-being or even to the long-term perpetuation of the bureaucracy itself. Corrupt, wasteful and inefficient behavior often is tolerated and sometimes even becomes a perquisite of office in "efficient" bureaucratic structures, so long as it avoids direct and serious interference with the master's power over persons and resources. These seeming contradictions are what Weber's approach points to so aptly.

This study concerns the core of Weber's approach, which portrays bureaucracy as a means of organizing the production of goods and services in a hierarchical social structure designed for the control of persons and resources. This general aspect of Weber's theory, which is operative regardless of the level of societal rationalization, sensitizes the analyst to complex, and often misunderstood, conditions resulting from the contradiction of domination and production in bureaucratic organization. The case study of the Roman Empire,⁴ which follows, illustrates the points made above. The value of this particular example is that the relations between domination and production are particularly clear and relatively unhampered by ideological debates

⁴ Although the analysis in this case study employs Weberian concepts, it is *not* derived from Weber's concrete analysis of antiquity. Weber (1968:969-70; 1976:364-5) expresses some concern about the role of bureaucracy in the decline of the Roman Empire. However, in one piece on Rome he (1950) stresses different factors than are discussed in my paper, and in still another essay on the topic (1976:336-66), although he gives some attention to bureaucracy, Weber's argument again emphasizes essentially different conditions than are stressed here. In conclusion, it should be understood that my paper is inspired by Weber's broader theoretical work, not his actual analysis of Roman society.

that surround modern social organization. Furthermore, since this is a historical case with a fixed periodization, the development of bureaucracy can be analyzed in relation to the long-term growth and eventual disintegration of the society. Finally, in Rome, as in modern society, bureaucratic organization grew to gigantic proportions and had substantial impact on the entire populace.

*Preconditions of Bureaucracy in the Roman Empire*⁵

According to Weber, bureaucratization is stimulated by a broad extension of administrative tasks (Weber, 1968:969). Furthermore, he argued that a tradition of internal peace, combined with an increased demand for order, is one of the conditions that sparks such expansion. Weber implied that bureaucracy is desirable in this situation because it is the most efficient means for coordinating the diverse activities of the masses involved in large-scale administration.⁶ Finally, the actual development and continued existence of bureaucracy requires a reliable revenue source, a stable system of taxation and a rationally calculable basis for regular compensation of bureaucratic officials (Weber, 1968:963, 968). Overall, Weberian theory implies that bureaucracy is most likely to emerge in large, urban

dominated states with monetary economies.

The Roman Empire was an urban civilization—cities and towns directed the course of its economic, political and cultural life (Jones, 1974:40; McEvedy, 1967a:84). The Empire included a massive geographical area and numerous provincial peoples (see McEvedy, 1967a:76–92; 1967b:2–23). Money, which was the dominant means of economic exchange in both urban and rural areas (Duncan-Jones, 1974:6–7), provided a rational basis for a relatively active revenue producing local and long-distance trade (see Loane, 1938; Wheeler, 1954; Pirenne, 1969; McEvedy, 1967a; 1967b). Although most of its population and political power was urban, Rome's primary source of wealth was from the land (Jones, 1974:35–7). Agriculture provided much more revenue than nonagricultural commerce and manufacturing (Finley, 1973:150–76). However, Roman farming was organized for monetary sale in urban markets, and was, for this reason, clearly different from the subsistence production of feudalism. Agricultural wealth, particularly that produced in the provinces, provided a stable, continuous source of tax revenue (Jones, 1974:82–3).

The Roman Republic⁷ (which preceded the Empire) collapsed after an intense period of internal conflict and disorganization (see Brunt, 1971:112–56). The early emperors used the military to restore the peace and order to which Romans long had been accustomed (see Brunt, 1971:61, 153). Furthermore, they extended the Empire's borders by the same means (see McEvedy, 1967a:74–85). The restoration of order and the governance of newly acquired territories swelled administrative tasks and promoted continued bureaucratic development. Initially, the emperors were extraordinarily successful, since their efforts culminated in the Pax Romana—a two-hundred-year period of prosperity, internal peace and hegemony over neighboring enemies.

⁵ The Roman Empire at its height in the second century A.D. extended from the Iberian Peninsula across Asia Minor and from England to the Atlas Mountains in North Africa (see McEvedy, 1967a:81). The Empire is usually dated from the beginning of the reign of Augustus in 27 B.C. until 476 A.D. when "the last remaining country of the West . . . had become just another German kingdom" (Grant, 1978:435–6). I have not dealt with the division of the Empire into its Western and Eastern sectors. Furthermore, the Eastern Roman Empire, which survived after 476 A.D. is not discussed. This elimination was necessary in order to keep the scope of the research somewhat manageable.

⁶ Weber (1968:972) stated, however, that the "power expansion" of the Romans did not result in a bureaucratic polity. Here, he is implying that Rome was not thoroughly bureaucratic in the fashion of modern monocratic bureaucracy. However, he recognizes at other points that Rome, despite its patrimonial elements (see fn. 8), did have a relatively advanced bureaucratic organization (see Weber, 1968:969–72).

⁷ The Roman Republic preceded the Empire and is usually dated from 509 B.C.—the approximate date of the Roman expulsion of the last Etruscan king—until Julius Caesar's first consulship in 59 B.C. (see Brunt, 1971:1).

Leveling and Plutocracy in the Roman Empire

Weber (1968:225,985,989) asserts that at least a relative social "leveling" accompanies bureaucratization. This involves a tendency toward formal law which emphasizes "abstract regularity of the exercise of authority" (Weber, 1968:983). On the other hand, Weber also suggests that bureaucratization promotes "plutocracy." Put in the context of other Weberian arguments concerning concentration and rationalization, these two seemingly contradictory points can be construed to mean that bureaucratization divides a society between those who control the bureaucracy and those who are controlled by it. In fact Weber (1968:985) states that the "decisive" fact "is the *leveling of the governed* in the face of the governing and bureaucratically articulated group, which in its turn may occupy a quite autocratic position, both in fact and in form." Bureaucratization erodes traditional statuses that hinder bureaucratic placement of officials. This does not eliminate hierarchy, but merely reshapes it to fit the needs of the nascent bureaucratic relations of domination. For example, Weber (1968:989-90) pointed out that leveling of feudal privileges benefitted the domination interests of the rising capitalist class. According to Weber (1968:987), bureaucracy is an instrument for "rationally organizing authority relations," adaptable to the interests of any group able to control it. Historically, the controlling groups have been those with military and economic power. As a rational structure of domination, bureaucracy has been a means for establishing, stabilizing and extending the domination of powerholding groups.

A *slight* leveling process occurred shortly before and after the establishment of the Roman Empire when the upper classes made small concessions (e.g., tax reform) to the masses that reduced slightly the impact of inherited status. Furthermore, the bureaucracy, through the proliferation of merit requirements, also contributed to the slight erosion of the traditional status hierarchy. However, there was no mass destruction of traditional statuses as occurred in early capitalism. In

the formation of the Roman Empire, unlike the capitalist revolution, the ancient ruling class maintained its position despite changes in social structure. The emergent bureaucracy was shaped to, and even took advantage of, the existing stratification system. As a result, Roman bureaucracy contained an important patrimonial strain.⁸ Despite this, its strong monetary and legal-rational attributes made Roman bureaucracy more similar to modernity than to feudal patrimonialism.⁹ In this section, Roman class structure will be discussed, but its links to bureaucracy will be analyzed more fully below.

Rome was stratified by wealth, political power and prestige, which usually coincided. Furthermore, Roman social structure was characterized by extreme verticality and low levels of social mobility (see MacMullen, 1974:88-120). Two aristocratic orders monopolized the most powerful and lucrative social, economic and political positions. It has been estimated that the senatorial order constituted approximately two-thousandths of one percent of the Roman people. The less powerful equestrian order (Equites) was probably less than a tenth of one percent of the population.¹⁰ Both orders were concen-

⁸ Patrimonialism (Weber, 1968:1010-5) refers to situations where the subject is bound to a master by loyalty and is required to support him with all possible means. This also involves decentralized domestic authority and land distribution to dependents. Weber (1968:1014) considered Rome a "patrimonial state"—where "the most fundamental obligation of the subjects is to the material maintenance of the ruler." This is contrasted with the bureaucratic, modern state where legitimate authority is much more impersonal, diffuse and normative. The Roman system contained patrimonial and bureaucratic elements—the balance between the two varied in different periods of the Empire. *At no time* did the Empire approach the degree of bureaucratization of modern states, nor was it ever as patrimonial as feudal society.

⁹ I do not want to push the comparison of Rome and modernity too far. I am only stating that Rome was far more bureaucratic and formally rational than feudal society.

¹⁰ The Roman orders were hereditary, but were still somewhat permeable. For example, new members were often assigned to the senatorial order by the Emperor. Also, occasionally senators lost their wealth and had their titles taken from them. Finally, money was the most important aspect of status in the Roman Empire. Thus, I will use the term *class* when referring to the different groups in the Roman social

trated in the most populous cities, but even there they constituted only a tiny minority (MacMullen, 1974:88-92). Ownership of very large amounts of wealth were required for maintenance of aristocratic title, status and position. Senators had to own property worth at least 250,000 times a laborer's daily wage, while equestrians qualified for their position with less than half of that estate. In most cases the aristocrats' wealth far exceeded the required minimums (Duncan-Jones, 1974:12, 17-32). In short, the two orders owned much of the Empire's wealth and controlled most of its social and political power. Despite the autocratic position of the emperor, the aristocracy can be considered a ruling class.¹¹

The régime was safe because it answered the needs and interests of the higher orders. No single man could govern the empire unaided, and every emperor was bound to look primarily to those orders for his advisors and officials; they had almost a monopoly of the education and experience required. . . . The emperors might persecute individual senators or Equites, but it did not even occur to any of them (not one was a man of original views) to assail the vital interests of the whole upper class, and if they had tried, they could not have survived. . . .¹² (Brunt, 1971:154-5)

Seneca once remarked, "[H]ow great a majority are the poor" (MacMullen, 1974:87). The rich and poor were recognized respectively as *honestiores* and *humiliores* (Finley, 1973:87). The state's attitude toward the humiliores was aptly

represented in the "law of debt" which applied exclusively to the poor in relation to the rich. According to this law, the defaulting debtor was forced into compulsory labor, a condition that could sometimes be extended to a debtor's children (Finley, 1973:40). This law represented only one dimension of the suffering of the underclass. The masses lived in abject poverty in the starkest, most unpleasant and dangerous conditions imaginable (see Mumford, 1961:205-48; Carcopino, 1973:22-51; MacMullen, 1974:1-87).

Furthermore, the classes were not spatially segregated, and thus they frequently met in the streets and other public places. The poor were expected to show fawning deference toward the rich and even to tolerate insult and/or physical violence without retaliation. Roman documents indicate that "honorable" and "good" were synonymous with wealth, as poverty was equated with "vile," "dishonored" and "ugly" (MacMullen, 1974:116-7). Romans believed that the "poor deserve to be held in contempt because they have no money" (MacMullen, 1974:116).

It has been estimated that slaves, the remaining segment of the Roman underclass, composed (at the height of the Empire's affluence) about a quarter of Italy's population and about one tenth of that in the provinces (MacMullen, 1974:92). Despite the notable exceptions of favored household slaves and certain successful freedmen (emancipated slaves), the plight of slaves was at least as unfavorable as that of other poor persons (see Finley, 1973:62-94). Slaves were fed, clothed and housed, but at the cost of their dignity and freedom. Frequent references to brutal treatment of slaves in Roman plays—"scourging, lashing, flogging, breaking ankles and torture and the ever-present fear of death by crucifixion"—provides insight into the nature of the master-slave relation (Cowell, 1975:102).

The Roman attitude toward hierarchy is expressed by the younger Pliny who said, "Nothing is more unfair than equality" (Brunt, 1971:155). The domination of the poor by the rich was brutal and direct without the mediation of ideological legitimation. Occasional largesse was not a sign of compassion, but was instead both

hierarchy (although slaves should be kept analytically distinct from the rest). Recent Roman social historians also have used the term class to discuss the Roman stratification system (e.g., Brunt, 1971; MacMullen, 1974). However, it is still crucial to keep in mind that the social groups referred to cannot be equated with modern social classes (see Finley, 1973:48-50).

¹¹ The term *ruling class* is not my own imposition upon the Roman system. I am following MacMullen's (1974:101) interpretation. Furthermore, one must not think of this group as being homogeneous in status, wealth and power.

¹² Despite this, there were tensions between the autocratic emperors and the upper classes. The intensity of these strains and conflicts reflected the social-economic situation and the particular personalities of the respective emperors (see Brunt, 1971:154).

a display of wealth and a means of securing servile clients. The resentment of the poor sometimes exploded in riots, arson or attacks on the rich (see MacMullen, 1966:163-91), but these disorders were almost always put down quickly, without severe threat to the social order. The extreme class division in Roman society existed before bureaucratization began. Once bureaucracy developed, it became a microcosm of the broader societal class domination as well as a means of perpetuating it.

Origins and Form of Roman Bureaucracy

Despite the abject condition of the masses and the tiny size of the power-holding group, the Roman ruling class had considerable continuity in its long rule (see MacMullen, 1973:101). Its hegemony was made possible by bureaucratic domination in which the military played a central role. Weber (1968:1149) considered bureaucracy the most rational extension of discipline. Furthermore, he (1968:1155-6) argued that "military discipline gives birth to all discipline." Roman bureaucracy first appeared as a routinization of the military discipline¹³ for which the legions were long famous (Gibbon, 1932:10-7). The legionary was sworn to unquestioned, exact execution of orders regardless of personal cost (Grant, 1974:xxvi-xxx). Furthermore, his officers were so unyielding in their demands for obedience that he often feared them more than the enemy. Finally, the legionary was almost always executing orders. When he was not fighting or working on public projects, he learned new skills or perfected old ones. The rigor of training is expressed in Gibbon's (1932:11) assertion "that the effusion of blood was the only circumstance which distinguished a field of battle from a field of exercise."

The Roman imperial military (see Garland, 1975; Charlesworth, 1951:29-48; Grant, 1974; Luttwak, 1976) contained

many of the characteristics of bureaucracy discussed by Weber (1968: 217-26, 956-69). It was "the earliest of the world's standing armies in which the soldiers were regularly recruited, and cared for, and finally pensioned off, by the state" (Grant, 1974:xv). The Roman military was a hierarchy of offices, each with fixed jurisdiction over a predefined set of activities. Impersonal administrative rules regulated relations between offices and people. There was also a chain of command and rigid supervision of lower offices by higher ones. Furthermore, there was even considerable emphasis upon files and written documents. The legionary received a fixed salary, was granted near-life tenure, had plentiful opportunities for advancement, received a bonus at retirement and even had veterans' benefits (Garland, 1975:114-7). The competent soldier knew he would be promoted and with some ingenuity could achieve high rank and generous material reward. As the bureaucratization of the Empire advanced, the emphasis on merit in the military ranks grew. For example, in the Late Empire "barbarians" were allowed to serve and could even earn high rank. Furthermore, the highest ranks, such as legionary commander (*legatus*), which were formerly reserved exclusively for the upper classes, were made open to all qualified candidates. The Roman soldier was a professional who underwent specialized training, acquired military discipline and received the predictable rewards of a bureaucratic career (Garland, 1975:112-6, 172; Grant, 1974:xvii-xxxiv).

The legionary's compliance with his commanders' direct orders was only one feature of Roman military discipline. Another important aspect, one that contributed greatly to the emergence of bureaucracy, was the coordinated administration of thousands of orderlies, accountants, messengers, checkers, surveyors, road builders and naval personnel (see Charlesworth, 1951:46-8; Grant, 1974:240-1). The emphasis on large-scale planning and calculation was evident in every aspect of Roman military activity ranging from the construction of the most advanced pre-modern system of roads (which were built

¹³ Military discipline and even military bureaucracy existed in Rome before the establishment of the Empire. However, the military definitely was more intensively professionalized and bureaucratized during the Empire (Grant, 1974:3-99).

for military use) to the military payrolls, which were managed with meticulous care (see Charlesworth, 1951:37-42). It is in this support service and broader administration that bureaucratic discipline emerged clearly from military discipline. Bureaucratic discipline retained the strict subordination of the military, but refined it into a more impersonal, rational form in which compliance occurs without the *direct* and continuous observation and intervention of higher officials. Their immediate presence is replaced by impersonal routines, rules, written memos, rewards and threats. The resulting bureaucratic coordination provided the Roman army with an advantage over less organized but numerically superior enemies (see Luttwak, 1976:1-5).

The Empire was instituted after the Roman Republic collapsed from corruption, class war and inefficiency (see Brunt, 1971:112-56). The first leader of the Empire, Augustus (27 B.C.-14 A.D.), was a charismatic military leader who commanded complete loyalty from the army. Augustus instituted extensive administrative reforms which established the roots of a militarized, *state bureaucracy*. He attempted to reduce corruption and improve administrative efficiency by transferring military discipline to the public realm. Civil servants were expected to take a military oath and were required to be either active military personnel or to have had extensive military experience. Public officials were expected to express the same exact compliance with orders that characterized the legions.

During the prebureaucratic Republic, taxes were collected by private corporations under government contract (Jones, 1974:151-85; Frank, 1920:139, 172, 224). The *publicani* (tax farmers) had broad powers because the methods of collection were not systematized nor highly regulated by the state. Since their first interest was profit, rather than the equitable collection of taxes, the publicani subjected provincials to gigantic corruptions (Jones, 1974:163-4; Mommsen, 1958:560-3; Mattingly, 1910:1-2). The gross injustices of this system contributed greatly to the conflicts of the Late Republic. The replacement of the tax-farming operation

with a public financial administration was an important step in the Augustinian pacification. Augustus desired to put imperial taxes and finance under the control of disciplined state officials guided by centrally administered tax rates, collection methods and accounting procedures. This was designed to increase state revenue, while at the same time mollifying the complaints of overtaxed provincials (see Mommsen, 1958:565-8).

In the Early Empire the administration of finance, as well as other branches of the Roman state, lacked "organs of transmission" (Homo, 1929:308). The early emperors simply utilized their own private staffs for state affairs. Emperor Claudius (41-54 A.D.), instituting the imperial secretariat, transformed this household service into a department of state (Homo, 1929:309-11). The establishment of a professional staff gave continuity to the administrative operations of the central government. This bureaucratic routinization reduced the impact of the nonrational personal attributes of individual emperors on the day-to-day functioning of the state. Emperor Hadrian (117-138 A.D.) continued this process by bureaucratizing the imperial *fiscus* (central treasury). Again, management by the imperial household was transferred to a professional ministry (Homo, 1929:307-8). These changes were only a small part of a very broad process of bureaucratic expansion. As the Empire grew, so did the number of ministries, departments and officials (see Homo, 1929:349). This growth contributed to the routinization and regulation of administrative activity in a hierarchical structure ruled by the emperor.

In the Late Empire (third century A.D.) intense bureaucratization was manifested in administrative unification (see Homo, 1929:321-43). Special regional privileges were removed, large provinces were divided into similar small units, civil and military powers were separated and uniform intermediate bureaucratic organs were created to link the central government with provincial units (Homo, 1929:341-3). As unification of the provinces proceeded, so did standardization of the individual official's administrative duties. Diverse roles were united in

"a single imperial civil service" (Homo, 1929:35). The Roman state gradually evolved into a full bureaucracy organized on the same basis as the military. In the state administration there was a strict order of rank defined by uniform rules. The "officials had an exact administrative status, which, in return for definite professional duties, entitled them to a variety of privileges" (Homo, 1929:358). The latter included career security with promotion based on seniority, a regular salary, exemptions from certain taxes and services, judicial privileges and honors (Homo, 1929:359-61).

Rationalization of law accompanied the formation of the Roman financial administration and broader state bureaucracy. As Weber (1968:998) suggested, the development of systematized law is central to the broader process of societal rationalization. Law is the primary means for transforming individual discipline into impersonal, bureaucratically coordinated routines. Written rules and formal means of administering them promote the standardization of action in specialized roles. Progressive bureaucratization of the Roman state involved instituting a large body of administrative law, which first appeared in the second century A.D., and grew steadily until the Empire's collapse. The state "bureaucracy demanded a cognoscible, uniform, and definite administrative law, and the jurists, who belonged to the bureaucracy, met the demand" (Schulz, 1946:139).

In the Republic, law was monopolized by persons, without expertise or training, purely on the basis of their aristocratic background (see Schulz, 1946:1-98). Accurate legal texts were unavailable and the entire administration of law lacked system. Legal competence was equated with oratorical grace, not with skill in applying legal knowledge. On the other hand, in the Empire upper-class status was no longer the exclusive qualification for legal office. The bureaucratization of the state and the growing body of administrative law it required necessitated the development of legal texts and relatively elaborate systems of legal knowledge. Thus, attorneys and jurists were more often expected to have expertise, spe-

cialized training and certification (see Schulz, 1946:139, 272-99). During the Empire a cadre of professional jurists became salaried members of the ministry of justice (see Schulz, 1946:100-1). This office brought legal experts together to extend and refine the legal superstructure of the state bureaucracy as well as the overall administration of justice.

Bureaucratization and Concentration of Power

Weber (1968:980) argued that bureaucratization goes hand in hand with the centralization of power over persons and resources. Although centralization contributes directly to domination, it cannot be separated from production. The bureaucratic master argues that efficiency in domination is necessary for efficiency in the production of services. This claim means that discipline in the ranks will sharpen the coordination of activity and ultimately result in improved service. However, as Weber implies, and the Roman case demonstrates, the tendency toward efficient domination tends to become an end in itself somewhat disconnected from any true commitment to service.

In the Roman Empire bureaucratization was accompanied by a symmetrical and related move toward totally centralized power (Homo, 1929:299). The official justification for bureaucracy was the maintenance of order, reduction of corruption and provision of basic state and municipal services. However, action based on these goals resulted in the transference of power from the senate and other representative bodies (dominant during the Republic) to the Emperor and his delegated officials. The central mechanisms of domination were streamlined by tactics couched in a mystifying rhetoric of bureaucratic efficiency. For example, Augustus instituted the division of the Empire into armed and unarmed provinces. The "safe" provinces as in the Republic, were administered by the senate, while the "threatened," or armed provinces were governed directly by the Emperor (Stevenson, 1939:101-4). The official reason for this action was the maximization of administrative efficiency

in the regions most prone to social disorder and/or invasion. The act may have appeared as a reduction in coercion since it demilitarized the central and most politically important provinces, but, in reality, it enhanced the Emperor's power by giving him absolute authority in a large part of the Empire, reserving his right to intervene in the remaining parts and empowering him to change the designation of provinces whenever he desired (see Homo, 1929:317). In this case, as in many others, changes aimed at improving efficiency also contributed to the Emperor's control of Roman society.

The successors of Augustus continued the dual processes of bureaucratization and centralization until any semblance of power was removed from elective bodies. For example, the election of magistrates was taken away from the popular assembly and given to the senate, which comprised the upper echelon of the ruling class. This was portrayed as another aspect of the rationalization of services. The senator's experience in official capacities, as well as that gained in governing his extensive private domain, allegedly provided him the required technical expertise for competent calculations about judicial, political and other official appointments (see Stevenson, 1939:106). However, even the power of the senate gradually was eroded (Homo, 1929:303). The emperors, who eventually gained full power of legislation and appointment, transformed the senate into a rubber stamp body by stacking it with their own appointees (Stevenson, 1939:108). The restructuring of the Empire, begun by Augustus, was characterized by "the gradual development of bureaucracy, the elimination of the senate from the work of administration and the concentration of it in the hands of the emperors" (Rostovtzeff, 1926:77-8). Even the financial reforms contributed to this process by transferring total power over state expenditures to the emperor and his staff. These bureaucratic reforms and their alleged contribution to administrative efficiency were the primary justifications for the change from republicanism to monarchism (Stevenson, 1939:147).

The bureaucratization of Roman law

concentrated "a monopoly of the development of the law in a government office, to codify the law and to control its application and execution in detail" (Schulz, 1946:100). Gradually, the command of the emperor replaced the citizenry as the supreme authority of state (Crook, 1967:20). During the Republic, jurists composed formulae of actions and defenses—*responsa*—that constituted new law. However, in the Early Empire, Augustus ruled that only jurists with special imperial authorization could have their *responsa* accepted as law (see Schulz, 1946:112). Later in the Empire, authorization of individual jurists was abandoned in favor of a law-making body—the *consilium*—appointed by the emperor (see Schulz, 1946:112-4). This permanent salaried group of officials in a standing organ of state (Schulz, 1946:118) provided the emperor with a central office to coordinate all judicial activities related to the formation and interpretation of law. From this time onward, the emperor, at minimum, had to approve new law, but more often he instituted it through edicts.

The early success of bureaucratization deflected citizens' attention from the autocratic centralization of power that accompanied it. Initially, bureaucratic professionalization reduced corruption and increased productive efficiency. However, as the number of appointive positions multiplied and elective ones declined, the problems that plagued the pre-bureaucratic Republic reappeared and were compounded by bureaucratic intransigence and red tape. Inefficiency and corruption grew in almost direct correlation to the heightened demands for certification and expertise (Rostovtzeff, 1926:460). In the Late Empire it is evident that domination, and not service, was the real goal of bureaucratization.

Achievement, Ascription and the Maintenance of External Social Hierarchy in Roman Bureaucracy

Roman bureaucracy had a patrimonial strain; it did not go nearly as far as modern bureaucracy in reducing the impact of arbitrary ascriptive characteristics. Modern ascription is less direct, fixed and for-

mal than the Roman type. Modernity puts more emphasis upon intergenerational advantages transmitted in a class-based educational system, than upon simple inheritance (see Weber, 1968:303, 998–1003; Bowles and Gintis, 1977; Collins, 1971). However, Roman bureaucracy, despite its patrimonial elements, also emphasized merit, training and credentials: Rome is more like modernity than any purely patrimonial system (e.g., feudalism), because it harmonized achievement with class ascription.

Weber did not envision a completely meritocratic process of bureaucratic appointment. It would have contradicted both his analyses of bureaucracy as a power system and his assertions about the “plutocratic” tendencies of bureaucratic societies. Appointment exclusively on merit would open vital offices to technically competent persons with interests opposed to those of the master. An able enemy in an important office is contradictory to “administrative secrecy” and to the “power interest of the given structure of domination *toward the outside*” (Weber, 1968:992). To avoid these problems, bureaucracies, whether patrimonial or highly rationalized, must screen officials on the basis of interests as well as ability.

Roman aristocrats actively participated in the bureaucratic process through their positions in high level state administration (see Stevenson, 1939:108). The rationality reflected in the bureaucratic emphases on skill, training and certification was not contradictory to the broader ascriptive universe within which they operated. In short, the qualifications purported to reflect merit were distributed with a systematic unevenness. The upper-class monopoly of them insured that able persons with the greatest interest in preserving the social order were placed in the highest offices. For example, senators usually were appointed to the most important political positions, while equestrians headed most of the high-level economic offices. Thus, the emperor relied on the aristocratic class to preserve the hierarchical relations of domination through their bureaucratic offices.

The lower and middle offices of the

Roman bureaucracy also illustrate the linkage of achievement and ascription. The actuaries, cashiers, accountants and other petty officials in the financial administration frequently were selected from slaves and freedmen (Jones, 1960:159–60). These individuals were often household slaves (or former household slaves) who had formerly managed the financial affairs of their aristocratic masters. They were well-qualified because they were trained from childhood to occupy roles of financial responsibility. Furthermore, their social and material interests were connected directly to the ruling class. It was their service to the elite that elevated these fortunate slaves and freedmen above the rest of the masses.

Another source of lower officials, especially those assigned to legal and police duties, was the military (Jones, 1960:161–4). Legionary privates from humble origins considered their selection for the civil service an important promotion and usually remained in civil bureaucratic careers permanently (Jones, 1960:162). Their military experience provided the necessary preparation for their bureaucratic roles and insured their commitment to preserving the social order. In general, Roman bureaucratization intensified the emphasis on achievement, but at the same time preserved and even improved the means of ascription. Lower bureaucrats were drawn from groups socialized for obedience. Furthermore, these groups had already benefitted from serving the ruling class in capacities similar to their new roles.

Roman education also reflected the linkage of achievement and ascription. Education was not compulsory or state financed, but schools were widespread and rather uniform (Bonner, 1977:328–33, 146–62). The school system had three basic levels: primary school, where students were taught basic reading, writing and arithmetic; grammar school, which emphasized grammatical study of Greek and Latin; rhetoric school, which stressed advanced language skills, especially oratory and debate (Bonner, 1977:165, 250–3). These schools were usually quite small (rarely more than 60 students and often

only ten or less) and were supported by direct student fees. The very wealthy often did not attend the schools, but studied at home with their parents and/or private tutors.

The content of Roman schooling was very different from modern education because it lacked technical training and science. Instead, attention was directed to "effective public speaking" which was "the prime objective of the standard school curriculum" (Bonner, 1977:331). Language was related intimately to public image and was a primary badge of worthiness. Eloquence was an important measure of a person's qualification for the legal profession, political life and high state office (see Bonner, 1977:66-89). Despite its nontechnological nature, Roman pedagogy was highly structured, methodical and thorough (Bonner, 1977:328-33). Rhetorical training was especially rigorous since it followed the rather formal and complex style of argument used in courts of law (Bonner, 1977:288-9).

The socioeconomic consequences of Roman schooling were not unlike those of modern education. Educational goals involved the nurturance of socially desirable personal characteristics important for occupational placement, political office and social prestige. Roman education was achievement oriented. Nevertheless, class ascription was preserved and even celebrated. Wealthy children simply had an overwhelming advantage with respect to the favored traits of the educational process. Rich Romans had highly refined linguistic skills which they carefully nurtured in their offspring. The sophisticated language training of wealthy children often culminated with trips to Greece for advanced training under renowned rhetoricians (Bonner, 1977:10-9). On the other hand, poor families could not provide an adequate early learning context, nor could they afford tutors or extensive schooling. Roman socialization and schooling assured persons their acquisition of cultural credentials of achievement consonant with their location in the social order. In education, as in the rest of Roman society, achievement was significant, but its sphere always was circumscribed by class ascription.

The Contradiction of Production and Domination and the Roman Decline

Thus far, it has been demonstrated that Roman bureaucracy constituted a concentrated and relatively rational structure of domination that ruled over a sharply stratified society. In the remaining section I will discuss how the increasing domination efficiency of this structure directly contradicted the productive (service) needs of the broader society and ultimately those of the bureaucracy itself. As the bureaucracy matured, domination evolved as its exclusive operative end, while the production of services was reduced to ideology. The resulting extreme efficiency in domination permitted the dominant class to perpetuate its control of resources without making necessary positive adjustments to severe tensions and breakdown in the social and economic spheres. Thus, efficient domination preserved, and even intensified, conditions which contributed to the erosion and eventual destruction of the socioeconomic substructure of the bureaucracy.

The third century A.D., a period of political strife and foreign invasion, was devastating to the Empire (Rostovtzeff, 1926:440). Between 235 A.D. and 284 A.D. there were 20 emperors recognized by the senate, approximately 20 others who claimed the throne with military support and numerous others who had similar aspirations (Finley, 1973:91). The military contributed to the divisiveness and disorder by making repeated, and often violent, political interventions. The ruling class eventually regained control of the structure of domination, but the Empire never recovered from the related economic and social upheavals. Furthermore, during and after this period the costs of national defense rose sharply, while revenue from plunder, foreign tribute and imported slaves was reduced drastically.

The political stabilization of the late third and early fourth centuries A.D. was achieved through increased bureaucratization of the state and military (Finley, 1977:140, 144). Emperors Diocletian (284-305 A.D.) and Constantine (306-337 A.D.) thoroughly professionalized and enlarged the military, and, in the process,

subordinated it to political authority. Civilian and military assignments were separated to prevent the military from meddling in political affairs (see Rostovtzeff, 1926:449–87; Barrow, 1970:163–74). In this way the military was brought under the firm control of the ruling class and its bureaucratic administration. The most general trends after the third century involved an increasingly powerful and centralized state bureaucracy controlled from the emperor's office. From this point onward, the exclusive response to economic crises, internal revolts and foreign invasions was "to tighten the bureaucracy and strengthen the instruments of the state, the army, the tax collector and the secret police" (Walbank, 1969:67; see Finley, 1977:140).

In the fourth century A.D. the ruling class was fully reestablished with an influx of new members from the military and civil bureaucracies (see Bernardi, 1970:42). Initial reforms brought hope of wealth redistribution, but the land—more than ever the primary means of producing wealth—remained concentrated in the hands of the tiny aristocratic class, preserving the radically stratified social order (see Bernardi, 1970:44–52; Finley, 1973:91–2). Although the extreme centralization of power in the emperor's office reduced the political independence of the aristocratic class, the imperial bureaucracy continued to draw its highest administrators from it. Furthermore, through its edicts and functioning, the state bureaucracy successfully protected and even extended aristocratic interests. As a result, the social hierarchy, based almost entirely on wealth, became more elaborate and petrified in the Late Empire (see Finley, 1973:51).

The massive, centralized bureaucracy required large surpluses for its maintenance and growth (Finley, 1973:90; Grant, 1974:398). The primary tax, which produced over 90% of the Empire's revenue, was on agriculture (Jones, 1974: 82–3). The high rate of taxation, which was accelerated sharply by bureaucratic expansion, (as well as other revenue problems), created new, heavy financial burdens borne almost exclusively by smallholders (Jones, 1974:86; Finley, 1973:91). The

large landowners had numerous ways to evade taxes completely, but even when these failed they were taxed lightly because they were entrusted with the job of assessment (Bernardi, 1970:58). The more that the revenue needs of the state expanded "the hotter the race for [tax] exemptions for classes and professions grew" (Bernardi, 1970:65). At the same time, tax pressures and penalties became almost unbearable for the humble classes. When exorbitant taxes were combined with periodic floods, drought or other natural catastrophes, the smallholder was crushed. Furthermore, when the tax rates were at their highest and most regressive level, the poor tax delinquent was treated without compassion. While the aristocracy's tax arrears were forgotten, the poor were forced to pay on time (Finley, 1973:91). When they could not, they lost their few possessions. Even the Catholic church abolished its tradition of granting asylum to "debtors of the treasury" in 392 (Bernardi, 1970:55).

Generally, the rich were able to maintain their wealth, despite the shrinking economy drastically weakened by the rising costs of bureaucracy. On the other hand, small independent producers were forced either to abandon their land or to put themselves under the protection of large landowners (Walbank, 1969:66; Bernardi, 1970:55; Jones, 1974:82–9). Aristocrats incorporated small holdings into their plantations, either by direct ownership or through clientage (the serf-noble relation that foreshadowed feudalism). This process contributed to more extreme concentration of wealth and power and further reduced agricultural production.

When conflict and economic decline intensified in the fourth and fifth centuries, the tendency was "to increase the number of officials, to simplify and standardize their duties, and to a certain extent to give the hierarchy a quasimilitary character" (Rostovtzeff, 1926:459). In short, the emperor attempted to stabilize the economy by extending the means of domination. The perpetuation of the social order depended upon the continual increase in both the efficiency of coercion and the rate of surplus extraction from the masses. However, the very efficiency of

bureaucracy in the preservation of the class-based relations of domination insured that the contradictions of the social system would remain unresolved.

The Roman ruling class utilized the bureaucracy to control the masses militarily, legally and financially. However, the domination system retarded the development of new social forces of production. The rates of extraction from the obedient human machinery were high enough that the dominant class never attempted to rationalize production. Instead, almost all rationalization in the Empire was limited to the sphere of domination. Thus, despite Rome's relatively advanced development, there never was any impetus toward technological revolution.

Efficient domination not only closed potential avenues of economic development, but it also devastated the traditional economy. The gigantic bureaucratic apparatus was extremely costly to maintain, since the horde of "officials and soldiers had become more numerous than the taxpayers" (Bernardi, 1970:52). The poor were not only burdened by the direct costs of this behemoth structure, but were also victimized by ubiquitous bureaucratic corruption (Rostovtzeff, 1926:460). Corruption was so widespread and accepted that it should be viewed as a systematic element of the domination system and not as foreign or pathological to it. Corruption allowed petty officials to make a living wage and high officials a luxurious one. In the Late Empire the pursuit of gain by any means possible was so much a part of bureaucratic functioning that moral prohibitions against corruption lacked structural foundation.

Each bureaucratic response to the growing socioeconomic crisis increased taxes and further strained the economy. After drastic erosion of the tax base, the rulers were forced, by economic exigency, to demand a greater contribution from large landowners. However, the latter had grown stronger from the expansion of their estates (and patrons) and could successfully resist the taxman. Furthermore, the military was occupied with the problem of foreign invasion and could not be used on a regular basis against the powerful landowners. In its last stage, the

Empire's disintegrating, urban-controlled economy began to germinate its opposite—the estate economy of feudalism. This constituted a regression at a time when technical advances were necessary to preserve the Empire. The main point is: the aristocracy's success in rationalizing domination deepened problems in production. Roman agriculture, which had begun to suffer the long-term negative effects (e.g., overcropping, deforestation) of its traditional method of "dry farming," required innovative changes if it was to continue supporting the urban population and its expensive social structure (Lopez, 1976:3–6). However, these obvious technical matters were ignored completely. Only the means and levels of surplus extraction mattered to the ruling elite.

The emperor and the high managers of the Roman bureaucracy operated within the practical sphere of its power system, concerning themselves exclusively with overriding, short-term power interests. The bureaucratic reaction to each step of the pyramiding crises was to extend and refine the means of domination. While these moves were couched in a service ideology, the ultimate end was individual gain and the perpetuation of the superordinate class. The leadership's responses aimed at preserving the existing relations of domination and their required rates of extraction without regard for the concrete social and economic problems which were destroying the system. As a result, the means of efficient domination became an important contributing factor to the eventual Roman collapse. The bureaucratic structure of domination contained the short-term threats to the social order, but in defending the latter, it preserved the very forces that were contributing to the destruction of the economy—the overconsumption of the ruling class and the costs of large-scale bureaucracy. In the end, the bureaucracy became self-contradictory and absurd.

Conclusion: Contradictions of Bureaucracy

The levels of domination and production in historical bureaucracies vary with

the concrete conditions of the particular organization and its social-economic context. This is a matter of empirical research that no theory could foretell. However, theory can sensitize the researcher to possible foibles of the conventional wisdom that portray bureaucracy in terms of its service ideals, rather than its actual operations. According to Weberian theory, a bureaucracy is always a domination system—by definition it must be based on hierarchy, discipline and control. On the other hand, the *actual* production of services for the general population is not necessary to the definition of bureaucratic organization. A historical bureaucracy may or may not deliver services.¹⁴ Secondly, the theory suggests that bureaucratization (the process of bureaucratic extension or intensification) entails a centralization of power for domination efficiency. The process heightens discipline and extends organizational control mechanisms. Bureaucratization may or may not improve the delivery of

services, but always is justified ideologically on the basis of service. Finally, the theory implies that bureaucracies propagandize the quantity, quality and value of their services, while suppressing information about productive inefficiency and coercion. Weberian theory points to the fact that accurate empirical analysis of bureaucracy must counter the organization's tendency to substitute a service ideology, which conceals exploitative extraction and coercion, for actual services.

The Roman case exemplifies the importance of clarifying the meaning of bureaucratic efficiency. Roman bureaucracy's extreme efficiency¹⁵ in domination contributed to the decline of necessary, productive forces. The overriding power interest of the Roman ruling class blinded them to the most necessary rational calculations in the societal and economic realms. The extractive success of their domination structure made critical evaluation of their power moves seem unnecessary. The Roman ruling class, in utilizing bureaucratic means to realize its immediate material and symbolic interests, contributed to the eventual destruction of the Roman social system.¹⁶ Most importantly,

¹⁴ Weber understood that modern bureaucracy had achieved a higher level of productive efficiency than any other historical social formation. As an historical entity, rather than a pure type, modern bureaucracy has been characterized by vast productivity. Despite this historical reality, efficient production is *not essential* to the Weberian pure type of bureaucracy. As a pure type it is a rational structure of domination characterized by discipline and coordinated activity. These attributes make it the best known means for systematically controlling large numbers of people and *potentially* a most efficient means of organizing production. However, actualization of potential productivity depends upon the substance of the "masters' " commands and the historical factors that condition their actions in controlling the bureaucracy. Modern bureaucracy, as a historical social formation, has unleashed beneficial productive forces as well as new threats to humanity. However, these facts cannot be understood adequately purely on the basis of its formally rational organizational structure. Instead, bureaucracy has to be analyzed in relation to societal historical development. The nature, quantity and quality of modern bureaucracy's production reflect the ends of its masters, conditioned by historical circumstance. The slight confusion between domination and productive efficiency, manifested in some of Weber's historical references to modern bureaucracy, derives from his incomplete analysis of the relation of rational bureaucracy to broader western capitalist historical development and particularly to the concrete history of its class domination, not to a failure to consider adequately technical competence and professional roles, as alleged by Parsons (1964:58–60n).

¹⁵ The efficiency of Roman bureaucracy was manifested in its dual abilities in containing the social and economic crises, while at the same time maintaining the massive wealth of the ruling-class. As the productive forces of the economy declined, the bureaucracy had to intensify its extractive mechanisms and also control increased dissatisfaction of the masses. The bureaucracy's success in these areas indicates its high domination efficiency.

¹⁶ It should be stressed strongly that this paper is *not* an attempt to pose a complete theory of the Roman Empire's decline or even to present the necessary or sufficient conditions causing it. The scope of the particular problem of research required that many contributing factors (e.g., technical aspects of Roman military strategy) be excluded from consideration, and others (e.g., the loss of revenue from reduced plunder, tribute and slave influx caused by the late Empire's inability to expand or, in the final stages, even to protect its borders) be given less emphasis than they would deserve in a more totalizing theory of the Roman decline. The limited goals of this paper have been to demonstrate how bureaucratic domination might have exacerbated the Empire's crises, and also to illustrate through concrete application certain features of Weber's theory of bureaucracy. Finally, it would be difficult, and perhaps even impossible, to provide convincing evidence proving that more substantively rational bureaucratic functioning, in the later stages of the Em-

this situation was *not* the result of bureaucratic breakdown or dysfunction, but instead evolved directly from *efficient* functioning in the sphere of domination.

The contradiction of domination and production reflects a broader cultural contradiction implied by Weber. Bureaucracy can be considered a social structural objectification of formal rationality.¹⁷ The social structure and the ideological form are both characterized by an obsession with technique and a disregard for substantive ends (the ultimate values that ground behavioral routines). Bureaucratic discipline and control are means to realize ends which are taken for granted *within* bureaucratic structure. Value-rational criticism, stressing the inability of bureaucratic routines to meet community needs, runs counter to bureaucracy's "objective discharge of business" (Weber, 1968:975) and to its calculation of means according to the principle of "least effort" (Weber, 1968:65-6). Since bureaucracy is a power system, the ultimate values that govern its routines are determined outside the bureaucratic line of authority by those who control it.¹⁸ Open dialogue about these

values, among officials, would violate the power prerogatives of the bureaucratic masters. Therefore, the system works to suppress open communication even when it concerns threats that bureaucratic routines pose to community survival. This underlying contradiction between formal and substantive rationality reflects the contradictory relationship of the power holder and the ruled.

The Roman Empire cannot be equated directly with the contemporary world because it lacked the extreme rationalization of modernity. In this respect, Weber's work is a testament to the unique nature of the modern system. However, the defining attributes of this system—science, technology, technical education, rational bureaucracy and vast productivity—*do not* insure correspondence between the ends established by bureaucratic masters and the needs (and interests) of wider communities, nor does it guarantee a reduction in the contradiction of domination and production. Due to its value neutrality, formal rationality *determines nothing* in the relationship between power relations and values. Its technical products can be another weapon of the power holder and/or a means for fulfilling community needs.

Despite indisputable advances in the quantity and diversity of production, some thinkers still argue that contemporary society is characterized by "the peculiar *fusion of technology and domination*, rationality and oppression." (Habermas, 1971:85; see Marcuse, 1968:1-18). They contend that the ability of modern bureaucracy to "deliver the goods" should not be confused with social and ethical "progress." Indeed, certain scholars believe that the rise of consumerism is a phase in the advance of bureaucratic centralization, planning and administration (Marcuse, 1964; 1968; Braverman, 1974; Ewen, 1976; Noble, 1977; Mandel, 1978). These critics suggest that freedom does not unfold automatically from the polymorphous production of consumer goods, but instead relates to community control of the process of production and harmonious development of the social and physical environment. Their point is that people may have

pire, would have long delayed the system's final collapse. However, despite this qualification, I concur with Finley (1977:153, also see 146-52) who states that "it was the inflexible institutional underpinning, in the end, which failed: it could not support the perpetual strains of an empire of such magnitude within a hostile world." In short, the bureaucracy cannot be blamed for all the diverse problems of the late Empire, but it did insure that they would not be solved.

¹⁷ I do *not* mean that formally rational ideas produce the structure of bureaucracy. I rather avoid the issue of the primacy of ideas or material structure and simply stress their correspondence and interrelation in this case. Furthermore, this is consistent with Weber's position emphasizing a balanced consideration of ideas and material reality (see Weber, 1958:183).

¹⁸ Weber implies that the ultimate power controlling bureaucracy is vested in a nonbureaucratic head. Because of this position, Weber has been criticized for portraying bureaucracy as a mere organ of power transmission. On the other hand, critics suggest that bureaucracy itself can be the source of power. Some theorists, exemplifying their arguments with modern states and particularly state-socialist systems, argue that the ultimate powerholders can be the highest level of bureaucratic personnel, making the bureaucracy the source as well as the instrument of power (see Lafort, 1974-1975).

full stomachs and still be overregulated, powerless and destructive.

The issues discussed in the last paragraph are still a matter of hot debate. However, the existence of the extreme rationalization of modern society is the obvious and pervasive reality that theorists of all persuasions attempt to explain. The less intensive rationalization of the Roman system and its inability to "deliver the goods" made its domination goals relatively transparent. On the other hand, modern bureaucracy's complexity, productivity and advanced means of regulating information insure its opacity to the masses. The "educational revolution" and modern communications do not necessarily improve the layperson's understanding of the modern world. In fact, they contribute to the proliferation of "experts" and arcane technical vocabularies that transform the simplest bureaucratic routines into ponderous scientific enterprises. Indeed, it is not surprising that the "common person" often thinks that every institutional practice has "a reason" that it is "too complex" for the nonexpert to grasp. I am suggesting that rationalization, with its utopian ideology of scientific and technical progress, contributes to a further closing of the dialogue concerning formal and substantive rationality (see Habermas, 1970; Mueller, 1970). The closed communication of bureaucracy, extended to the community outside the bureaucracy, has vastly increased the information control of the bureaucratic master. As a result, the danger of confusing ideology with reality is much greater today than in simple systems, like Rome, where oppression is direct and relatively unadorned by complex legitimations in democratic dress. This is *the reason* for preserving Weberian skepticism in investigations of modern bureaucracy.

INEQUALITY AND POLICE STRENGTH: CONFLICT THEORY AND COERCIVE CONTROL IN METROPOLITAN AREAS*

DAVID JACOBS

University of Maryland Baltimore County

American Sociological Review 1979, Vol. 44 (December):913-925

Conflict theorists have frequently argued that differences in economic resources give elites the ability to control the coercive apparatus of the state. Pronounced economic differences also provide elites with a strong need to maintain order so that ongoing relationships will not be disturbed. Because a strong police force is the most direct way to maintain order, one logical implication of conflict theory is that law enforcement personnel should be most numerous in metropolitan areas where differences in economic resources are greatest. Cross-sectional analyses of large SMSAs in 1960 did not always support this hypothesis. But when data from 1970 were analyzed the results invariably showed that unequal metropolitan areas were likely to have more police and other law enforcement personnel.

Although it has often been debated, the connection between the economic power of elites and the coercive apparatus of the state remains an unresolved issue in sociology. Close attention to this problem is not surprising since hypotheses about this fundamental relationship are a major component of both the radical and conservative images of society. If societies are held together by force for the benefit of those who have more, than one can expect that those charged with creating and enforcing the law will be especially responsive to the wishes of the highest class. But if social order is based on democratic consensus, then other more numerous classes should be at least as influential.

These themes have been diligently pursued in the literature on stratification and political sociology (cf. Weber, 1968; Lenski, 1966; Collins, 1975). Recently, with the emergence of the conflict perspective on the legal order, those who study crime have also been drawn into this perennial debate. Because of this recent innovation a subdiscipline that was once

isolated from the theoretical core of sociology (Taylor et al., 1973; Turk, 1969) may now shed new light on fundamental questions about the nature of society.

This possibility exists because of the questions that are being raised by conflict theorists. Instead of seeing the law as impartially administered for the benefit of the majority, conflict theorists maintain that the control of crime and deviance proceeds in accord with the wishes of those with power who use this control to further their own narrow interests. It follows that research which addresses this issue must focus on perennial sociological disputes about the correct image of society.

My intent is to see if a hypothesis derived from the conflict model of the legal order can be used to predict one outcome that is in the interest of economic elites. The exact question I seek to answer by use of quantitative techniques is whether differences in economic power lead to stronger agencies which specialize in coercive control.

The Literature

The initial work on social control which used power as an explanatory device was eclectic in its treatment of resources. For example, Dickson (1968) and Duster (1970) wrote about the bureaucratic imperatives and resources which shaped the administration of the drug codes. Gusfield (1963) and Platt (1969) emphasized a variety of middle class interests while Roby

(1969) argued that a pluralistic combination of many interest groups determined how prostitution was to be regulated in New York.

This work was very useful because it demonstrated that law did not emerge from consensus. But the findings do not seem to cumulate. With such conclusions in mind, the only thing that can be said about the relationship between social organization and social control is that a circulation of interests based on a variety of resources shapes the legal order (Taylor et al., 1973). A summary of these results does not answer more fundamental questions about the exact social conditions which give particular groups the ability to control the law and its administration.

Recent theoretical work has stressed economic power as the basis for control over the legal order (Chambliss and Seidman, 1971; Chambliss, 1976; Quinney, 1974; 1975; Taylor et al., 1973). For example, Chambliss writes that "middle class organizations are for the most part unable to combat or counteract the forces of classes who control the economic resources of society" (1976:92). Instead, "The dominant economic class through its use of the legal system is able to preserve a domestic order that allows its interests to be maintained and promoted" (Quinney, 1974:21). Historical studies by Chambliss (1964) and Graham (1972) and quantitative analyses by Jacobs (1978) and Jacobs and Britt (1979) support this contemporary emphasis on economic resources and economic power.

Towards an Operational Hypothesis

This emphasis can be used to develop a test of conflict theory that is similar to the operationalization used by Jacobs (1978). If the possession of money almost automatically confers power in western societies (Blalock, 1967), then an unequal distribution of this crucial resource should lead to outcomes preferred by the rich. Power is a relational concept involving comparative differences in resources. Therefore, when economic resources are distributed more unequally, economic elites will have the greatest capacity to achieve their aims. It follows that *the*

more there are inequalities in the distribution of economic power and economic resources, the more one can expect that the social control apparatus of the state will conform to the preferences of monied elites.

Thus, if the economic emphasis in conflict theory has merit then differences in economic resources will give elites the ability to control the legal order.¹ Economic inequality also makes this control a necessity. According to Chambliss and Seidman (1971:33)

the more economically stratified a society becomes the more it becomes necessary for dominant groups in society to enforce through coercion the norms of conduct which guarantee their supremacy.

This argument can be applied to modern societies by noting that conflicts between the haves and have-nots occur within a social organization where state violence can be called out or appealed to as a threat (Collins, 1975). In societies where production is organized by markets, an ability to call out this threat should be vital for elites. This is so because the differences in rewards that result from unbalanced exchange make it likely that at least some members of the more numerous dependent classes will attempt to use force in order to overcome their subordinate position (Blau, 1964). It follows that the dominant economic class "constantly sponsors . . . legislation that will help to achieve stability so that ongoing relationships can be sustained" (Chambliss, 1976:76).

In this society the major institution responsible for the coercive maintenance of stability and order is the police. This point is supported by Bittner (1975) when he says that even when the police are selected for noncriminal tasks it is because they are specialists in the use of

¹ For additional evidence that this formulation is consistent with conflict theory, consider the statement by Chambliss (1976:100) that "Only secondarily and then only in minor ways does the criminal law reflect the value consensus, the public interest or the shifting and weighing of competitive interests. A model more consistent with the realities of legal change must take into account differences of power which stem largely from differences in control over economic resources of the society."

coercive force. Thus, because conflict theory predicts that economic differences provide elites with both the ability to control coercive institutions and the need to maintain order, there should be a close, positive relationship between economic inequality and the number of police in metropolitan areas.

The Police and the Protection of Elites

There are less theoretical reasons for believing that economic elites have a vital interest in a strong police force. According to Silver (1966), the police were initially developed in order to protect the "peace loving propertied classes" from the poor. In times before the police, public order had been maintained by either the army or an irregular force of rural property owners called the yeomanry. Neither arrangement was satisfactory. The yeomanry was both prone to overreact—a favorite tactic was the cavalry charge—and often perceived as the instrument of the upper classes. Use of the army involved an even more dichotomous control system because this force was expensive to maintain and just as ill-adapted to meet day-to-day needs for intermediate measures.

The police represented an effort to overcome these disadvantages. This organization was designed to penetrate civil society in a way that was impossible for the military. Such a specialized force could begin to prevent crime and control the "dangerous classes" on a daily basis. Thus, economic elites created a "... bureaucratic police system that insulated them from popular violence, drew attack upon itself, and seemed to separate the assertion of 'constitutional authority' from that of social and economic dominance." Silver and Parks (1970:11-2) argue that the contemporary police have similar uses.

Other facts support the argument that a strong police force benefits elites more than other classes. In general, it can be said that the modern police force is a reactive agency with a limited capacity to detect or prevent the many illegal activities which are comparatively inconspicuous (Reiss and Bordua, 1966; Reiss, 1971;

Wilson, 1971; Rubenstein, 1973). The police have infrequent access to private areas (Stinchcombe, 1963). In addition, the ratio of policemen to possible offenders is infinitesimal.

These factors make the discovery of illegal behavior or its intent very difficult because the available procedures allow only the most gross assessments about deportment. For example, the policeman in charge of an area can make decisions about who should be stopped and investigated only on the basis of clearly apparent anomalies in a suspect's behavior (Rubenstein, 1973). These simple cues are much too crude to interfere with the activities of most lawbreakers and this means that the police are ineffective unless criminal intent is obvious. It follows that when a crime is reported, a policeman has only a few minutes to make an arrest. After these few minutes most suspects become invisible in any large city (Rubenstein, 1973).

One result of these circumstances is that conventional street crime is difficult to control in low income sections of the city where the street criminal and innocent bystanders frequently share many characteristics (Rubenstein, 1973; Wilson, 1971). But if policemen are numerous, their reliance on "that which is out of place" (Rubenstein, 1973) should be more effective when the residents of affluent neighborhoods must be protected from street criminals whose lower status is often quite visible.² In addition, riots which begin in low income areas can be confined to those sections of the city by a strong police force. It follows that even if we ignore the real possibility that the police are most responsive to demands for security by the affluent, it is still likely that a strong police force is better able to protect these citizens.³

² Note however that the converse does not occur. Since the police only control the streets (Rubenstein, 1973) even the most effective department cannot protect less affluent citizens from white-collar crimes that are often committed by the rich.

³ These facts partially explain why the poor are generally the most frequent victims of crime and riots. It follows that the police often concentrate their forces in low income areas to make attempts to alleviate these problems. However, this concentration will still benefit elites if redistributive violence is

This differential in effectiveness implies that if the police become unexpectedly deactivated in any large city, the rich and powerful have much to fear. Several case histories of police strikes support this assertion. In 1919, fifteen hundred officers struck the city of Boston and left just one hundred and fifty men on duty (White, 1965). After a tentative period of incremental violations in low income sections, large crowds began to loot expensive stores in the downtown area. By the time order was restored, more than one million dollars in property damages had resulted (Ziskand, 1940). But this strike was not a complete surprise since many business establishments and wealthy home owners were able to hire private guards and avoid serious damages (*New York Times*, Sept. 11, 1919).

Clark's (1975) account of the recent Montreal strike is more instructive because there was no time to hire additional protection. In 1969, almost all of this normally peaceful city's thirty-eight hundred police unexpectedly walked out and left 200 Canadian state police to maintain order. Again, after apparently starting in poorer sections, violations spread to other districts. The number of bank robberies rapidly increased. After the banks closed, many expensive jewelry stores were robbed and after these closed, calls began to come in from food and drug stores. Citizens in affluent neighborhoods also suffered. Later in the same evening, crowds began looting in the downtown area leaving 156 establishments with smashed windows and empty display cases. The three most expensive department stores were heavily damaged.

Powerful elites were victimized in additional ways. Two hundred independent taxi drivers used fire bombs to mount an effective attack on the company which held an exclusive franchise on service to the airport. The mayor's luxurious restaurant was deliberately sacked along with several of the more expensive hotels. Other symbols of English domination in

this ethnically divided province were also singled out for special attention.

At a minimum, these case histories imply that descriptions of the uses of the first police force (Silver, 1966; Parks, 1970) have contemporary merit since the inverse relationship between class and victimization no longer seems to hold when the police become unexpectedly deactivated.⁴ This evidence also supports theoretical arguments that differences between the resources of elites and other groups give elites a vital interest in a strong police force. Thus, if it is the case that the coercive apparatus of the state is controlled by those with economic power, then we can expect that the most unequal metropolitan areas will have the greatest number of police and other law enforcement personnel.

METHOD

Difficulties with Previous Studies

Several researches have looked at the statistical relationship between inequality and police strength but these studies have serious flaws. No theoretical justification was attempted and both analyses used inappropriate units. Dye (1969) looked at data collected from states in 1960 and found no relation between a Gini index computed from personal incomes and police per capita. But there is good reason to believe that any connection between economic inequality and police strength would occur only in large metropolitan areas where informal controls are lacking (Jacobs, 1978; Price, 1966). Because states are heterogeneous units which include rural districts and small towns and since a simple mathematical check of

most likely to emanate from these areas. Subsequent examples will show that this is a reasonable assumption.

⁴ It is not necessary to argue that all police strikes have led to the increased victimization of the affluent. For a variety of reasons, criminal violence did not expand in many cities when the police struck. Either the strike was predictable so that substitute officers could be temporarily used or only a limited number of officers participated or some other idiosyncratic event prevented an increase in violations of all kinds (Bopp, 1971; Ziskand, 1940).

The important point for this analysis is that when these temporary restraints were insufficient and the strikes did result in more violations, a much greater proportion of these crimes was directed at elites.

Dye's results reveals anomalies, his findings should be reinvestigated.⁵

Foley (1977), on the other hand, used 300 counties in the northeastern United States and found less consistent results. In this study of the correlation between a Gini index computed on family incomes and expenditures for police was negligible for all counties but when Foley looked at 55 counties within northeastern standard metropolitan areas the zero-order correlation rose to .69. However, limited statistical controls on the percentage of non-whites and median family incomes caused considerable attenuation in the partial correlation.

In any event, an investigation of the effects of economic inequality should not use counties. Consider a relatively poor city surrounded by affluent suburban counties. As long as the measurement of inequality is confined to these fairly homogeneous units, each county will appear to be equal, but if all contiguous counties in this metropolitan area are combined their inequality score will rise dramatically. Counties (and cities) are artificial units in other ways. Affluent suburban residents often have economic interests and considerable political influence in adjacent cities (Banfield and Wilson, 1963; Dahl, 1961). Because violators can also cross city boundaries, elite influence may be used to insure that cities maintain a strong police force as a first line of defense between low income areas and the affluent suburbs. It follows that both inequality and the number of law enforcement personnel should be measured using large standard metropolitan statistical areas because the interactions that concern us are *not* restricted to cities.⁶ In any event, this

methodological decision does not have much effect on the conclusions since an analysis that uses cities and less valid inequality scores gives results that are almost as strong as those found by using SMSAs.

Design and Operationalization

In this study, I used a cross-sectional analysis of all SMSAs with a population greater than 250,000 in 1960 and 1970. Economic inequality was measured with standard deviations computed from data on family incomes taken from the census enumeration of incomes in metropolitan areas (see Blalock 1972:87 for the formula to compute *S* from grouped data). This measure of inequality has particular advantages for a study of elites because it is sensitive to income differences created by the presence of high income recipients. Income distributions are skewed so a measure that is based on squared deviations from the mean will be most affected by the largest incomes although the distribution of all other incomes will still contribute to variation in *S* (Alker and Russett, 1966. For precedent in the use of this measure of economic inequality see Jencks et al., 1972 and Chiswick and Mincer, 1972). Note also that by definition inequality is a relational characteristic rather than an individual one. When inequality is measured income receiving units must be compared. This means that an attempt to examine the connection between inequality and police strength must use ecological aggregates as the unit of analysis.

I measured police strength with census statistics on the number of police and detectives per 100,000 population who were employed by local governments and with the number of police, detectives, sheriffs, bailiffs, marshals, and constables per 100,000 population employed by municipal governments. This second dependent variable is worth examination because many localities use these different occupational groups for the same purposes.

⁵ Dye implies that his coefficients are beta weights because he makes comparisons of the predictive strength of different variables within equations. However, something is amiss because it must be that in any regression equation where the results are given in beta weights the sum of the products of each beta weight and each independent variable's correlation with the dependent variable must equal the R^2 (Walker and Lev, 1953:322). Application of this formula to Dye's results indicates that either he reports unstandardized coefficients and then erroneously compares them or there was an error in his calculations.

⁶ It is common for larger municipalities to sell police services to adjacent local governments (Os-

trum et al., n.d.). It follows that the use of cities rather than SMSAs would also result in artificially inflated totals since some police manpower is not used within these cities.

Alternative explanations for variation in police strength were operationalized as follows. Metropolitan areas with many blacks may have more policemen because the presence of this disprivileged minority leads to fears of crime and riots. This variable was measured with census statistics on the percentage of blacks in an area. Metropolitan areas may also have more police if they had direct experience with riots. This variable was operationalized by aggregating Spilerman's (1970; 1971; 1976) data on the number of riots in cities between 1961 and 1969 to create a total score for each SMSA. Because joblessness may contribute to crime and disorders, metropolitan areas with a higher percentage of unemployed workers may have stronger police departments. This variable was measured with census statistics on unemployment.

Relatively affluent metropolitan areas can afford more police protection. The best measure of resource level is mean family incomes but this indicator has substantial intercorrelations with other independent variables. One solution is to substitute median family incomes for mean incomes and report these additional results. This means that I will report two sets of equations. One set will be less complete but the intercorrelations between independent variables will be reasonable. In the other set, the most optimal measures will be used but higher intercorrelations will be present.

Areas with more crime should have more policemen. But the use of F.B.I. statistics on crimes known to the police as an independent variable is not consistent with ordinary least-squares assumptions about reciprocal causation and measurement error. These rates are widely acknowledged as unreliable. In addition, they are often manipulated for bureaucratic ends (Kitsuse and Cicourel, 1963). Sophisticated police administrators can increase their budgets with inflated statistics so a component of the relationship between the crime rates and police per capita may be the result of systematic exaggerations which result in more law enforcement personnel. Since there is no way to estimate the size of these distortions and because the number of crimes in

an area should be an important determinant of police strength, I will also report additional analyses which include this independent variable.

Owners of small retail establishments have a natural interest in a strong police force. Their losses from crime are disproportionately high (Reiss, 1969) so one common reaction is to make frequent requests for continuous surveillance (Rubenstein, 1973). The most effective measure of this concept was the number of drugstores and liquor stores per 100,000 residents taken from the census of business.⁷

There is evidence that social control is more difficult in populous communities (Jacobs, 1978; Price, 1966). Thus, larger communities may find that they must employ more policemen. I used the log of an SMSA's population to measure this effect. This measure has strong correlations with other indicators so it was used only in the second set of equations with substantial intercorrelations between the independent variables. Finally, because social relationships are often held to be qualitatively different in the southern region of the country, I also entered a dummy coded one if the majority of an SMSA's population was in one of the eleven southern states.⁸

It follows that four equations will be used to estimate each dependent variable in 1960 and 1970. Two equations will use the crime rates but that variable will be excluded from the other set. Two equations will be restricted to independent variables with reasonable intercorrelations while the other two will employ the most optimal measures but the intercorrelations between independent variables will be substantial.

ANALYSIS

Multivariate Analysis

Table 1 shows the intercorrelations

⁷ In fact, no other reasonable combination of the categories of retail activity contained in the census of business was an effective predictor of the amount of law enforcement personnel.

⁸ States classified as southern were Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, Tennessee, Texas, and Virginia.

^b To correct for positive skew the dependent variables in 1970 are logged to the base 10.

between all variables in both 1960 and 1970. Note that the four correlations between economic inequality and measures of police strength are quite strong although other independent variables had equivalent relationships with the 1960 dependent variables.

Table 2 shows the results of multiple regressions computed on the 1960 data. Beta weights for the number of retail establishments vulnerable to crime were always significant but the coefficients for inequality were only significant in five of the eight equations.⁹ It follows that metropolitan areas with a disproportionate number of drug and liquor stores were most likely to have more police. In addition, it is probable that unequal SMSAs were also likely to have stronger law enforcement agencies although this effect was less robust in the face of collinearity.

This was not the case when the 1970 data were analyzed. Regardless of the controls that were introduced, the results in Table 3 show that economic inequality always had significant effects. Beta weights for the number of drug and liquor stores per capita were also comparatively strong. The percentage of blacks, however, had less substantial effects although they were significant in all equations. Finally, it is interesting that even though the number of riots in a metropolitan area had moderately strong zero-order correlations with the number of police and law enforcement personnel, this variable was ineffective when other relevant factors were controlled.¹⁰

⁹ Tests of significance are useful when the data are taken from an entire universe instead of a sample. As Nambodiri et al. (1975:10) and Blalock (1972:238-9) point out, when such tests are applied to data from populations the observed distribution is compared with a random process. In other words the observed distribution is treated as randomly sampled from a population of all possible, indefinitely repeated experiments.

¹⁰ It has been argued that the use of ratios as indicators may lead to faulty estimates if the same term appears in two variables. For example, the correlation between two ratios with population in each denominator may be artificially high (Schuessler, 1974). Note, however, that the inequality measure does not share terms with the dependent variables. In addition, when the analysis is confined to independent variables with moderate intercorrelations, the index of inequality does not share terms with any

Table 2. Multiple Regression Analyses of Police Strength in 1960 (Reported Coefficients Are Beta Weights. N = 96*)

Significance Levels * .05 level ** .01 level.

* Equations which include the crime rates are computed on 91 cases. Five SMSAs had to be dropped because of differences in the enumerated areas.

^b In equations with moderate intercorrelations between independent variables resource level was measured with median family income. This concept was measured with mean family income in the other equations.

These results can be summarized by noting that unequal SMSAs probably had more law enforcement personnel in 1960 but the relationships were much stronger and more consistent in 1970. It follows that the 1960 results offer some support for conflict theory while the coefficients computed from 1970 data provide good evidence that differences in economic resources lead to more public employees who specialize in coercive control.¹¹

variable. But other independent variables do use population in their denominator. To control for this effect, if an independent variable had population in its denominator in the previous analyses, its numerator was regressed on population and the residual from this equation was substituted for the original independent variable. This strategy removes all shared terms. The coefficients found with it are equivalent to those reported in Tables 2 and 3. Beta weights for inequality continue to be substantial.

¹¹ Other measures of inequality and racial subordination had little effect on the dependent variables. Coefficients for indicators sensitive to racial inequality like the ratio of black to white median family incomes or the percentage of black families below the poverty line were insignificant. Alternative measures of economic inequality that were less sensitive to the presence of high income families like the Gini index or the percentage of all families below the poverty line also had negligible effects. In addition, no relationship between the dependent variables and various measures of density or the percentage change in population could be found. Finally, there was no discernible tendency to pay lower wages so that more policemen could be hired since the correlation between median police salaries and police per capita was positive ($r = .46$). Even when the comparative wages in an area were loosely con-

Additional Evidence

Other competing explanations for the results can also be eliminated. First, the evidence does not support a hypothesis that economic inequality has effects on police strength because of the activities of less affluent income recipients. If the percentage of families in each income category used by the census is correlated with the dependent variables, the relationships are weak for all but the two highest categories in both years. For example, in 1960 the percentage of families with incomes between \$15,000 and \$25,000 and those with incomes above \$25,000 were correlated with police per capita at .57 and .53, respectively. In 1970 the two highest categories were \$25,000 to \$50,000 and \$50,000 plus but the correlations were almost identical at .57 and .52. Because correlations for other income groups never get above .42 and since there is a consistent downward trend as incomes diminish, it is evident that in areas where middle and low income families are most numerous there is no tendency to hire additional police.

Note, however, that these high income variables cannot be used as substitutes for the measure of total inequality. Problems with severe collinearity between the per-

trolled by dividing median police wages by all median incomes the correlation between police per capita and this ratio was still weakly positive at .13.

Table 3. Multiple Regression Analyses of Police Strength in 1970 (Reported Coefficients Are Beta Weights. N = 121)

centage of high income families and other important independent variables often make it impossible to enter these measures in an equation. When these variables can be used the measure of total inequality is more effective but this result is predictable. Recall that the inequality variable always had stronger zero-order relationships with the dependent variables. Thus, it appears that a variable which measures *differences* in economic power is more useful in this study than one that measures only the presence of high income recipients.

Another possibility is that economic inequality heightens the power of elites, but since this group has a greater sense of civic responsibility, unequal areas will have more public services of all kinds. The available evidence also makes this hypothesis difficult to believe. For example, the correlation between inequality and local government health workers per capita is -.03 while the relationship between inequality and the number of social and recreational workers per 100,000 residents is .19. In addition, there is no relationship between inequality and the proportion of families below the poverty line who were recipients of public assistance.

But there is a more comprehensive way to evaluate this hypothesis. If inequality has a positive correlation with the percentage of *all* local government employees who specialize in law enforcement then

unequal areas must have fewer public employees providing other services. This correlation is .53 for both the percentage of policemen and the percentage of all law enforcement personnel and these relationships continue to be substantial when statistical controls are introduced. Thus, where differences in economic resources and economic power are greatest, there will be more law enforcement personnel hired at the expense of other public service workers.

DISCUSSION AND CONCLUSIONS

Research described by Wilson (1975) shows that saturating an area with more police has no effect on either the crime rates or crimes cleared by arrest. If methodological problems with crimes known to the police and other difficulties are ignored, these findings imply that beyond some threshold level it is irrational to demand more police. But this research says nothing about the minimal number of police that are necessary to control unpredictable events like riots. In any event, the notion of rationality assumes that information is complete (Simon, 1959). But when there is considerable uncertainty about the exact point where additional policemen are no longer worth their additional cost it may be wise to err in the positive direction. Thus, inevitable imperfections in knowledge mean that de-

mands for more police may be quite rational for some groups.

One reason for this is purely economic. Local taxes are highly regressive with respect to income (Netzer, 1973; Shannon, 1973) so the affluent have less to lose from local expenditures for public services. It follows that any private costs for protection which can be shifted to local governments will be borne largely by other classes. Furthermore, because elites must contribute a comparatively small amount of their income for additional law enforcement personnel, a strong police force not only helps to preserve their position but also costs them less.

On a more general level it can be said that pluralists have consistently deemphasized the importance of economic cleavages as a determinant of political and legal outcomes. But perhaps this burial was premature. Certainly those results show that at least one important local outcome is heavily influenced by differences in economic resources. A good part of this disagreement can probably be attributed to differences in methodology. When they study political outcomes, pluralists have generally relied on the direct observation of interest groups and their effects. But the political activities of elites will often be disguised and inaccessible to an outside observer. Observational techniques also mean that the researcher becomes preoccupied with the details of a few decisions without being able to generalize about outcomes in a large number of political units. It follows that this method may not be the best way to see if economic cleavages are important.

It should also be emphasized that elites are not the only beneficiaries of expanded police services. Large segments of the poor also gain although it is unlikely that this group benefits as much as elites.¹² It follows that the use of those results to contradict pluralistic theories of local power violates an implicit assumption that is a fundamental element of that perspective. In order to make their picture of

community power credible, pluralists invariably stress issues that involve a fixed sum relationship between interest groups so that one group's gain requires equivalent losses by other groups. But this imagery does not fit many issues because losses and gains are neither equivalent nor inversely related. In this specific instance, many groups voice demands for more police but the evidence suggests that departments will be strongest only when conditions give influence to economic elites and a few retail store owners.

Thus, a finding that pronounced economic cleavages lead to more policemen not only supports conflict theories of the legal order but it also substantiates claims made by critics of pluralism. Now instead of relying on the reputational or positional approaches and arguments about the insensitivity of observational methods, those who are skeptical of the pluralistic model of local power have some quantitative evidence that differences in economic resources are a significant determinant of one important local outcome.

Finally, the coefficients also indicate that the police tend to be strongest in metropolitan areas where there are many stores that sell either drugs or liquor. Because no relationship between the number of law enforcement officers and other kinds of retail activities could be found, this consistent result implies that only a few store owners are successful when they demand more police protection. Thus, it appears that two factors contribute to stronger police departments. Metropolitan areas will have more policemen when differences in economic resources allow elites to exercise more influence and when there are many potentially vulnerable retail outlets for narcotics and alcohol.

Summary and Conclusions

Conflict theorists have often argued that legal institutions are subject to the preferences of economic elites who use this control to maintain their ascendant position. One logical implication of this view is that an unequal distribution of economic resources will give elites both the ability to control the coercive apparatus of the state and a vital need to maintain order so

¹² This is particularly the case since the provision of additional police officers comes at the expense of other public services.

that ongoing relationships can be sustained.

The most direct way to maintain order is with a strong police force. Therefore, it was hypothesized that law enforcement personnel would be most numerous in metropolitan areas where an unequal distribution of resources favored influence attempts by the affluent.

The analysis of large SMSAs in 1960 provided moderate support for this hypothesis since regression coefficients for inequality were significant in five out of eight equations. But when data from large SMSAs in 1970 were analyzed, the results always confirmed this prediction since inequality was significant in all eight equations. Note however that the coefficients cannot be used to eliminate an additional explanation for the strength of law enforcement agencies since areas with many drug and liquor stores also had more policemen in both years.

Another aspect of the results is instructive. Metropolitan areas with more blacks had stronger law enforcement agencies in 1970 but this effect was not present in the 1960 equations. Thus, economic and racial cleavages were better predictors of police strength after a decade of well publicized social upheavals which may have been threatening to elites. Finally, an additional analysis showed that unequal metropolitan areas had fewer public workers in fields other than law enforcement. Therefore, in areas where differences in resources favor the affluent, one can expect that more resources will be spent on coercive control but this will be at the expense of other public services.

It follows that these results and those found by Jacobs (1978) and Jacobs and Britt (1979) provide quantitative evidence that conflict theory can be used to predict the behavior of institutions that specialized in social control. This study also provides a bridge between conflict theories in criminology and more general theories of stratification. In particular, the results are consistent with Weber's (1968) contention that those with a dominant position in market exchanges will always seek state protection from redistributive violence. Thus, where production is organized by markets, coercion may no

longer be used as a direct cause of inequality as it was in premarket societies (Lenski, 1966). Instead, it is more likely that the government's monopoly of coercive violence is kept in reserve to ensure that asymmetrical exchange relationships will not be disturbed. This study shows that this reserve is stronger when economic differences between elites and nonelites are greatest.

THE PARADIGM CONCEPT AND SOCIOLOGY: A CRITICAL REVIEW*

DOUGLAS LEE ECKBERG

University of Tulsa

LESTER HILL, JR.

*Jacksonville State University**American Sociological Review* 1979, Vol. 44 (December):925-937

The thesis of this paper contends that many sociologists who have attempted to apply Kuhn's argument in analyzing the status of sociology have misunderstood, or have refused to accept, the central meaning of his paradigm concept. In this paper we first clarify the notion of paradigm as explicated by Kuhn and by Margaret Masterman, and note that the "exemplar" is the central element in the concept. We then analyze the usage of the concept by sociologists who have attempted to ascertain the paradigmatic status of sociology and we focus in particular on the work of Friedrichs and that of Ritzer. In so doing, we show that they have concentrated almost exclusively on the less important, more general meanings of the paradigm concept and thus lose the major thrust of Kuhn's argument. Possible reasons for this misuse are discussed. Finally, we argue that sociology has relatively few exemplars, lacks a clear-cut puzzle-solving tradition, and tends to operate from discipline-wide perspectives. In this regard, sociology is not a mature science; attempts to treat it as such within Kuhn's framework are misdirected.

INTRODUCTION

Undoubtedly one of the more influential and controversial scholarly books to emerge in the last few decades is Thomas S. Kuhn's (1962; 1970a) *The Structure of Scientific Revolutions*. The impact of this work has been felt in such diverse fields as history, philosophy, political science, anthropology, sociology, theology, and even art (Hollinger, 1973). Students of each of these disciplines, in assessing the

relevance of the paradigm concept for their own concerns, have begun arguments which continue to this time (see, for example, the wry account in Perry, 1977).

Although these discussions are interesting in their own right, it is the discussion among sociologists that is of primary concern here. There have been several attempts to use Kuhn's scheme of scientific structure to analyze the development of sociology. The results of these attempts have been far from satisfactory. In fact, there are almost as many views of the paradigmatic status of sociology as there are sociologists attempting such analyses. As we will demonstrate, sociology is seen as possessing anywhere from two to eight paradigms, depending on which analyst one chooses to cite.

One explanation of this phenomenon is that a number of sociological theorists have misused the paradigm concept. The

Revised version of a paper presented at the annual meeting of the Southwest Social Science Association, Dallas, Texas, April, 1976. We are indebted to Sheldon Olsen, Simona Draghici, Jeffrey C. Alexander, and the anonymous referees for their helpful comments on an earlier draft of this paper. The authors assume joint responsibility for this paper; the names have been listed alphabetically.

result of this misuse has been that the concept has come to be used in ways which Kuhn never intended. In some cases it has taken on attributes which he specifically disavows. Multiple interpretations of the term have had the effect of allowing sociologists to cite Kuhn as a source while, at the same time, they are not taking seriously the implications of his position.

We use the term "misuse" advisedly. As we will show later, Kuhn's original paradigm formulation left considerable room for variance in interpretation. Still, two aspects were central to the term even prior to 1962 (for example, Kuhn, 1957:ix): the cognitive nature of paradigms and the community structure in which they appear. Moreover, the writers discussed here were largely aware of Kuhn's (1970a) later explication of the concept. When they miss either aspect of paradigm, they misuse the concept in a technical sense, even when their arguments are otherwise compelling. Their general positions may command respect, but their reliance on Kuhn is ill-founded.

In this paper we shall (1) provide a clear explication of the paradigm concept by following definitions and uses of the term by Kuhn (1962; 1970a; 1970b; 1974) and Masterman (1970), (2) show the various ways in which sociologists have used the concept, (3) attempt to ascertain just why such a theoretically important contribution has been so misused, and (4) provide our own version of the paradigmatic status of sociology. This paper will not consider the validity of Kuhn's overall position.

COGNITIVE ASPECTS OF PARADIGMS

In one respect it is not surprising that the paradigm concept has been misconstrued. Kuhn himself admits that his original explication was obscure (Kuhn, 1970a:181). Even a sympathetic critic (Masterman, 1970) suggests that Kuhn uses the term in at least twenty-one different ways, but she also notes that the various usages fall into three main categories: metaphysical, sociological, and construct paradigms. By the time the concept found its way into general sociological dis-

course, Kuhn had made several efforts to clarify its meaning. Others, however, seemed more intent on stretching it. As Perry (1977:40) notes, "... if Kuhn has been concerned to delimit the meaning of his key terms, others have been engaged in extending them" (see Heyl, 1975:62).

Without necessarily agreeing with the specific labels employed, we can agree with Masterman that paradigm refers to beliefs at three different levels. At the broadest level of generality (corresponding to what Masterman calls "metaphysical paradigms," or "metaparadigms") are unquestioned presuppositions. Kuhn does not overtly grant such usage, but Masterman finds it abundant in his work, and it is the only kind of paradigm to which his philosophical critics have referred (Masterman, 1970:65).

More restrictive is Kuhn's disciplinary matrix (corresponding roughly to Masterman's sociological paradigm), which represents the shared commitments of any disciplinary community, including symbolic generalizations, beliefs, values, and a host of other elements (Kuhn, 1970a:182ff.). A disciplinary matrix may be seen as the special subculture of a community. It does *not* refer to the beliefs of an entire discipline (e.g., biology), but more correctly to those beliefs of a specialized community (e.g., phage workers in biology). This is an important point which will be discussed in more detail below.

The most restrictive use of paradigm is reserved for what Kuhn calls an "exemplar." Corresponding to what Masterman labels an "artifact" or "construct" paradigm, this term refers, first of all, to the concrete accomplishments of a scientific community. What many of his critics (and supporters) have failed to see is that it is the exemplar which is the most central meaning of paradigm for Kuhn. Compared with disciplinary matrix, for example, he states that exemplar is the deeper of the usages (Kuhn, 1970a:175; 1974:463, 471ff.).

Since the crucial meaning of the paradigm concept for Kuhn is the exemplar, it is important that we understand in detail what he means by this term. By "exemplar," Kuhn means "initially, the

concrete problem-solutions that students encounter from the start of their scientific education, whether in laboratories, or examinations, or at the ends of chapters in science texts" (1970a:187). To such problem-solutions, Kuhn adds "at least some of the technical problem-solving found in the periodical literature that scientists encounter during their post-educational research careers and that also show them by example how their job is to be done" (1970a:187).

Masterman helps us to begin to unravel some of the confusion associated with the paradigm concept by noting that a "paradigm is a concrete 'picture' of something, A, which is used analogically to describe a concrete something else, B" (1970:77). Masterman is telling us that the important question is not what an exemplar *is* (such that one can enumerate it) so much as what it *does*. Kuhn never quite succeeds in making this point explicit, which may explain some of the confusion surrounding his argument. Where he has failed, however, Masterman (1970:70) succeeds:

[if] we ask what a Kuhnian paradigm *is*, Kuhn's habit of multiple definition poses a problem. If we ask, however, what a paradigm *does*, it becomes clear at once . . . that the construct sense of "paradigm," and not the metaphysical sense . . . is the fundamental one. *For only with an artifact can you solve puzzles.* (emphasis in original)

Again:

What Kuhn must be feeling his way to, in talking about an artifact which is also a "way of seeing," is an assertion, not about the *nature* of his artifact, but about its *use*: namely, that being a picture of one thing, it is used to-represent another. . . . (Masterman, 1970:76-7, emphasis added)

It was following Masterman's comments that Kuhn began making more explicit the *function* of an exemplar:

The resultant ability to see a variety of situations as like each other . . . is, I think, the main thing a student acquires by doing exemplary problems. . . . After he has completed a certain number, which may vary from one individual to the next, he views the situations that confront him as a scientist in the same gestalt as other members of his specialists' group. (Kuhn, 1970a:189)

The term, paradigm, is taken from linguistics, where it refers to patterns of declension, conjugation, and so forth, of types of words, such that a given word will make sense in different contexts of use (e.g. *amo*, *amas*, *amat*). Kuhn's most straightforward demonstration of a paradigm element involves the various derivations of Newton's $f = ma$, such that in various contexts the formula comes to be $mg = md^2/sdt^2$, $mg\sin\theta = -md^2/sdt^2$, $m_1d^2s_1/dt^2 + k_1s_1 = k_2(d s_2 - s_1)$, and so on (Kuhn, 1974:464 and passim). The point is that symbolic (and other) generalizations in science are applied in areas where it is nowhere immediately apparent that they fit. Fitting is accomplished through a series of examples given to a student which indicate that generalization A can be modified to become generalizations A', A'', A''', and so forth, as the situation changes. All of these make sense in terms of the base generalization which spawned them.

The function, then, of an exemplar is to permit a way of seeing one's subject matter *on a concrete level*, thereby allowing *puzzle solving* to take place. This is central for Kuhn because it is the basis for his notion of normal science, and normal science is the basis for his demarcation between science and nonscience (Kuhn, 1969; 1970b:245-6). For a discipline to be a science it must engage in puzzle-solving activity; but puzzle solving can only be carried out if a community shares concrete puzzle solutions, or exemplars. It is the *exemplar* that is important, not merely the disciplinary matrix, and certainly not merely the general presuppositions of the community. The latter may be important (see Holton, 1973; 1975), but they do not direct ongoing, day-to-day research.

Something more should be said about the interrelationships among the three levels of paradigm. Perhaps the most important point is that they are embedded one within the other. That is, the greater structure (the metaphysical paradigm) acts as an encapsulating unit, or framework, within which the more restricted, or higher-order, structures develop.¹ A spe-

¹ In this discussion "higher" refers to more restricted levels of belief-consensus. Shared exem-

cific disciplinary matrix will not develop within just any arbitrary *Weltanschauung*. An exemplar will be even further restricted. Before exemplars could develop, say, in sociology, one would have to accept some basic sociological pre-suppositions. It must be stated immediately that the presence of a disciplinary matrix does not guarantee in any way that normal science will develop. Kuhn is attempting to describe the structure of a science, not give guidelines for its accomplishment. In Kuhn's (1970b:245) own words:

... I claim no therapy to assist the transformation of a proto-science to a science, nor do I suppose that anything of the sort is to be had. ... If ... some social scientists take from me the view that they can improve the status of their field by first legislating agreement on fundamentals and then turning to puzzle solving, they are badly misconstruing my point.

Returning to the interrelationships among the three levels of paradigm, we find that each lower level has directive power over the next higher level such that the development of the higher level can be seen as an articulation of the lower. There is a reflexive side to the relationship, however. A "revolution" is that reconceptualization of a lower order belief made necessary by the presence of anomalies in the next higher level. Anomalies are possible only because each higher level of belief is more constrained than the previous level. When we reach the level of the exemplar we are speaking of almost purely concrete applications of a highly structured body of belief. It is at this level that inconsistencies can and do become apparent. Such inconsistencies appear in the course of active puzzle solving.

STRUCTURAL ASPECTS OF PARADIGMS

As the foregoing discussion illustrates, "paradigm" (more precisely, "exem-

plars, for example, are at the highest level of consensus, while metaparadigms are low. Lower orders of belief, here, serve as bases upon which the higher orders are constructed.

plar") indicates a quite specific type of cognitive framework. What is equally important, however, is the structure of the group which collectively holds a paradigm (see Kuhn, 1970a:176-81; 1970b:251-3). Specifically, a paradigm presupposes an integrated community of practitioners. Ongoing puzzle solving, in fact, occurs only when a group exists which shares a consistent body of belief such that a consensus emerges with regard to the phenomena one investigates, the methods one uses, and so forth.

Kuhn's discussion of the training of new scientists exemplifies this group context of research. New students in a discipline are painstakingly taught the matrix of beliefs which mark the discipline. The change from confused undergraduate to sophisticated scientist is a massive one. Students first learn a basic sort of knowledge, then begin learning applications of it. Later they begin learning the specialized body of knowledge which constitutes their scientific specialties.

In all cases, the neophyte scientists are dependent on their texts and professors for explication of what may at first appear incomprehensible. A relatively unproblematic learning process is possible only where there is a lack of dispute over what constitutes real knowledge, the "truth" of the situation. It is only after long-term tutelage that students learn where to look for puzzles—research topics to which paradigms virtually guarantee a solution.

Thus, a paradigm locks its practitioners together within a fairly rigid, highly elaborated framework of beliefs. This is not a serendipitous overlapping of elements from various perspectives. It is made of the consensual beliefs of a self-contained community. No analysis which neglects the communal nature of a paradigm can capture the essence of the concept. It is so important that Kuhn claims that if he were to rewrite *The Structure of Scientific Revolutions* he would "open with a discussion of the community structure of science" (Kuhn, 1970a:176, emphasis added). What is truly surprising is the number of sociologists who have not seen or have preferred to ignore "the sociological base of [Kuhn's] position" (Kuhn, 1970b:253).

SOCIOLOGISTS AND THE USE OF THE
PARADIGM CONCEPT

As we have seen, a paradigm refers to that thing which allows scientists to go about solving the puzzles they continually generate. When used by sociologists, however, the term comes most often to mean no more than a general theoretical perspective, or even, as we shall see, a collection of elements from several more or less distinct perspectives. As such, the paradigms spoken of by sociologists are nebulous, shifting entities, indicating whatever one wishes them to indicate, and are limited only by the theorist's imagination. While a specialized scientific community can be readily isolated on the basis of (1) quite specific beliefs concerning subject entities and (2) professional relationships among active scientists, perspectives can be formed at will, depending only upon which elements in intellectual discourse one wishes to emphasize. To put it another way, the sociological pie can be sliced many ways, but it is problematical as to whether any of these slicings indicate paradigmatic structure.

Table 1 presents twelve different sets of authors who view the organization of sociology in at least ten fundamentally different ways—each claiming to present "Kuhnian paradigms." The earliest among these authors is R.W. Friedrichs (1970; 1972) who makes quite clear his debt to Kuhn, and whose initial description of paradigms follows Kuhn's closely (Friedrichs, 1970:4). In application, however, Friedrichs radically revises the concept. Having admitted that Kuhn's original scheme was not intended to be used in the analysis of social science (e.g., 1962:ix-x), Friedrichs (1970:18-9) proceeds to attempt just such an analysis. He concedes that there is no dominant paradigm in sociology (of the kind necessary for normal science), and that such may not be possible. (Of course, from Kuhn's perspective, paradigms, or exemplars, are not seen as being discipline-wide in the first place.) He then spends much space arguing about the distinctive nature of social science, and later in his work actually criticizes Kuhn for

failing to notice the difference (Friedrichs, 1970:324-5).

Friedrichs' basic contention is that in sociology there are two orders of paradigm. On one level are those paradigms which Friedrichs sees as much like those in natural science. Two of these are primary: (1) the system, or consensus paradigm (Friedrichs, 1970:25) and (2) the most popular contender, the conflict paradigm (Friedrichs, 1970:45). This type of paradigm is supposed to correspond to the "fundamental image a discipline has of its subject matter" (Friedrichs, 1970:55, emphasis removed).

However, according to Friedrichs, this primary order of paradigms is *not* the most crucial one for the social sciences. There is a "more fundamental paradigmatic dimension" in the social sciences, and that is the "image the social scientist has of *himself as scientific agent*" (Friedrichs, 1970:55, emphasis in original. For an evaluation of this "paradigm as a form of personal salvation," see Perry, 1977:42-4). Friedrichs contends that this level of paradigm is the more basic and has a controlling power over paradigms of the other order. Finally, Friedrichs maintains that there are two fundamental paradigms: the priestly and the prophetic. The choice between them determines the choice between the conflict and consensus paradigms (1970:290-1; also see Westhues, 1976, for an elaboration and extension of this argument).

Considering Friedrichs' lower-order paradigms, it is evident at once that they correspond, at *best*, to disciplinary matrices, and perhaps not even to that level of paradigm, as they are *discipline-wide* and do not divide sociology by our community criterion. Friedrichs' higher-order paradigms are even more metaphysical. We do not argue that such cognitive sets do not exist. We *do* hold that they are not group-bounded and that they affect no more than minimally the *direction* of research. Neither order of paradigm is of a concrete enough quality to support a puzzle-solving tradition. Postulation of such a structure implies that research is *not* strictly paradigmatic, that it does *not* utilize artifacts. Here, science (or at least

Table 1. Twelve Sets of Sociological "Paradigms"

<u>Carroll (1972)</u> ANOVA	<u>Douglas (1972)</u> (1) Hypothetical- Statistical (2) Phenomenological (?)	<u>Friedrichs (1970)</u> (1) Priestly (2) Prophetic

social science) comes to be seen as a purely political undertaking in which research traditions and anomalous findings play no active parts. Such implications are quite different from those associated with Kuhn's notion of paradigm.

An important point that Friedrichs disregards is that Kuhn is interested in scientific activity as revolving about a technical or instrumental knowledge. Concern with oneself as an actor is concern with something fundamentally different. It is not surprising that the behavior postulated to accompany such divergent concerns would be strikingly different. The question is how an author could premise such differences yet state that the same model of behavior underlies both concerns.

It might be noted that Friedrichs (1972) does take note of Kuhn's clarification of the paradigm concept. Following Kuhn's discussion of the importance of exemplars in the development of a discipline, Friedrichs develops an idea for a type of exemplar for sociology which he calls "the dialectic." However, he once again

so revises the concepts that they lose their original content. In this case he argues that a stream of articles in major journals functions in the same way as do concrete accomplishments within a coherent research tradition. There are, of course, similarities between the two, but unless the streams themselves are part of a research tradition they do not lend themselves to technical puzzle solving.

Friedrichs is not alone, of course, in contending that the consensus/functional approach is one of the major paradigms in sociology. Lehman and Young (1974), Kuklick (1972), and Bottomore (1975) all claim that functionalism (along with various competitors) is a paradigm in sociology. The same argument against Friedrichs advanced above applies here. Functionalism and its contenders are simply *not* paradigms in the sense that Kuhn intended. They are not widely recognized achievements which practically and conceptually define the course of future research. If we read Kuhn correctly, the exemplar concept (paradigm) must indi-

cate a much more imposing authority (cf., Bryant, 1975:356ff.).

In each of the cases cited above the focus has been on what might be termed discipline-wide "paradigms"; they are not specific to substantive areas. Sociologists, with few exceptions, have stuck to this level of analysis. One writer goes so far as to claim that true specialties are not possible in sociology, that general ideas are of the greatest importance (Urry, 1973:466). Be this as it may, the greater number of theorists reviewed here have offered just such broad analyses (see, for example, Sherman, 1974; Walsh, 1972; and Wilson, 1970).

Although the sociologists cited above feel that there are, or have been, paradigms in sociology, there are others who feel that the discipline is still pre-paradigmatic. Among these are Denisoff et al. (1974:2-3), who contend that while sociology does not yet have a paradigm, there are certain *paradigmatic assumptions* underlying sociological work. From their discussion it is evident that they accept a broad definition of paradigm in that what they portray is an overarching matrix of beliefs (Denisoff et al. 1974:3-7).

Another author, Andrew Effrat (1972), feels that a rigorous application of the paradigm concept forces us to conclude that sociology is preparadigmatic. In his discussion of the concept, Effrat explicitly chooses to employ a "[c]onsiderably looser and more generous use of the criteria," and holds that such usage suggests "that there have been a number of reigning paradigms" (Effrat, 1972:11fn.). Having chosen this path, Effrat (1972:12-4) offers what is perhaps the most elaborate method yet for generating paradigms in sociology. Specifically, he employs a typology based upon the interaction of two dimensions: (1) level of analysis (micro vs. macro) and (2) substantive component emphasized (material, affective, interactional, and idealist or symbolist). He thus generates eight paradigms for political sociology alone, and he admits that there may still be more.

At the end of a complexity spectrum away from Effrat is Michael Carroll (1972), who presents us with a series of

assumptions which he contends underlie the "analysis of variance paradigm."

While not maintaining that this is the only paradigm in sociology, Carroll does state that it is extremely widespread. As is the case with most of the writers discussed above, Carroll deals only with discipline-wide ideas. He is also concerned with the methodological, rather than the substantive, assumptions of the perspective (though he shows interrelationships between the two). Moreover, while Kuhn concerns himself with the functions of paradigms, Carroll is concerned exclusively with their dysfunctions. In addition, Carroll's discussion does not directly consider the generation of puzzles, but rather the treatment of puzzles arising from other sources (cf. Kuhn, 1961). As an overarching generalization, Carroll's paradigm *may* be seen as a component of a disciplinary matrix, but *not* as an exemplar.

A view of paradigms similar to that of Carroll is the one presented by Jack D. Douglas (1971). Douglas holds that a hypothetical-statistical paradigm overlays most of sociology, infusing those competing paradigms which are, indeed, attached to substantive concerns. He argues that a difference between natural and social science lies in the fact that in natural science paradigm choice exists only between areas of specialization, while in the social sciences it exists across specialties (thus, they are "multiple paradigm"). Yet, following this, he states that the hypothetical-statistical method is seen to be "*the* valid paradigm for research methods in *any* area of specialization" (Douglas, 1971:46). His concern is closely related to that of Carroll and, in trying to place it in a Kuhnian framework, he opens himself to the same criticisms.

We come now to what may be the most mixed attempt to apply Kuhn's paradigm concept to sociology—that of George Ritzer (1975). Ritzer's analysis is at once promising and frustrating. It is promising because, in the abstract, Ritzer understands the concept, understands that it has been misunderstood by sociologists, and concerns himself with the *functions* of paradigms (e.g., Ritzer, 1975:5). It is frus-

trating because, having once grasped the concept, Ritzer then lets it escape him entirely.

As far as we know, Ritzer is the only sociological theorist who makes a clear distinction between disciplinary matrix and exemplar, and he is one of the few who recognizes that a paradigm need not apply to a discipline as a whole. Having seen all of this, Ritzer proceeds to act as if just the opposite were the case. First, his paradigms are discipline-wide. Secondly, and more important, Ritzer *dismisses* the importance of exemplars and self-assuredly asserts that "[t]he paradigm is the broadest unit of consensus within a science" (Ritzer, 1975:7). We have already seen how broad definitions lose the essential features of paradigm for us. Of course, it is perfectly admissible to analyze science in terms of metaparadigms: E. A. Burt (1954) did so in the 1920s. The problem with such an analysis in this particular instance is that it misses the puzzle-solving/puzzle-producing, community-based nature of exemplars, and gains nothing new for us. Kuhn does not present us merely with the old idea that metaphysical assumptions structure perceptions in science; rather, he presents us with an analysis of the *place* of such assumptions in the *social organization* of science.

Ritzer's analysis then, like most others, lacks a necessary specificity of referent. For if paradigms are the broadest units of consensus, how can they serve "to differentiate one scientific community (*or sub-community*) from another" (Ritzer, 1975:7)? The broadest unit of consensus in science will be some form of western scientific world view, or perhaps a linguistic organization of the world such as those discussed by sociolinguists since Whorf (1956).

In this regard, Ritzer's division of sociology into "social facts," "social behavior," and "social definitions" paradigms must be seen as arbitrary, while his statement that each paradigm has "an" exemplar is naive in terms of puzzle-solving traditions. Interestingly, what were seen as conflicting paradigms by others—structural functionalism and conflict theory—are, in Ritzer's scheme,

incorporated into a single social facts paradigm (e.g., Ritzer, 1975:57).

It might be asked how perspectives seen as so diverse by others can be placed within a single paradigm. The answer must lie with the theorists. We can only assert that paradigms are *unified* bodies of belief shared by a cohesive *community*. Ritzer joins what others put asunder, and he is far from alone in this regard. The sociological literature on paradigms is strewn with different pie-slicing arrangements. Friedrichs might argue that all three of Ritzer's paradigms fall within the consensus (or priestly) mode. Walsh and Wilson put all of the above (with the possible exception of social definitions) into a positivistic paradigm, while Friedrichs could hold that both positivistic and phenomenological paradigms are priestly. Sherman might assert that the two are separate paradigms joined by a third, emancipatory paradigm, and Douglas seems to argue that a statistical paradigm underlies all three of Ritzer's groups.

Those theorists who generate paradigms on the basis of arbitrary schemes miss *both* the cognitive and the structural aspects of the paradigm concept. Those who speak of conflicting schools of thought (e.g., Kuklick, 1972; and Westhues, 1976) are at least in the same ballpark as Kuhn. They, at least, recognize that his argument concerns structured groups.

In this context, the work of Nicholas Mullins (1973) deserves mention. Mullins is one of a number of sociologists of science who have applied the paradigm and related concepts to analyses of group structure in scientific communities. Recently he has used sociometric techniques developed for such studies (supplemented with a goodly supply of intuition) to indicate that there definitely are coherent theory groups within sociology. The groups he finds do not correspond, in any simple way, with those postulated above. Mullins contends that the variables he employs indicate that the structure of these groups corresponds rather well with that of theory groups in natural science.

*Although we are getting ahead of our argument, it is relevant to inquire here if the kinds of *ties* operating within natural

Table 2. Nicholas Mullins' (1973) Empirically Grounded Sociological Theory-Groups

(8) Radical-Critical Theory

science groups are at work within sociological groups. There is reason to doubt that the cognitive content shared by a sociological theory group is precisely the same as that indicated by the term paradigm. Mullins' analysis is directed at group structure rather than at cognitive ties. He admits that his techniques are useful for constructing indicators of group cohesiveness rather than for presenting the group relationships themselves. His roots are more in Derek Price's (1963) invisible colleges than they are in Kuhn's paradigms. Moreover, while occasionally mentioning "paradigmatic content," Mullins is content to call his structures "theory groups." Furthermore, he notes that while sociology seems to fit the model of group structure found in the natural sciences to a decent degree, there are some differences. Notably, (1) there is a lack of delineation between different stages of group development within sociology, but not in natural science, and (2) sociology appears to have a *looser* social and intellectual organization than does natural science (Mullins, 1973:130-6). More will be made of this later.

A problem with analyses such as that presented by Mullins (1973:321) is related to his admission that his methods merely present indications of social ties. These social ties might be concrete indicators of communities, and could, therefore, serve as evidence for the existence of paradigms. They are, however, necessary but not sufficient conditions for paradigms. In our search for paradigms in sociology then, Mullins' techniques can indicate the structure, but not the content, of theory groups. What is certain is that we cannot be sure that (1) sociology has the same structure as does natural sci-

ence, or that (2) the patterns that do exist are indicative of paradigm-sharing or paradigm-bounding.

MISUSE OF THE CONCEPT—WHY SOCIOLOGISTS?

If Thomas Kuhn is to be believed, paradigmatic status is determined by the workings of a unified group of specialists. If such is the case, one cannot divide a discipline freely into paradigms, but must be constrained by both group structure and cognitive consensus. Why then do sociologists appear to feel free to divide their discipline into various, inconsistent perspectives and call these divisions "paradigms?" It appears that we can look in two directions for the source of this dilemma: either to Kuhn, himself, or to the sociologists who have attempted to use his framework.

The simplest answer might be that Kuhn has failed to define his concept clearly enough, and that writers have been victims of ambiguity on his part (for criticisms of Kuhn's position in various respects see Lakatos and Musgrave, 1970; Shapere, 1971; Sheffler, 1967; and Trigg, 1973). This answer has some merit especially if we remember Kuhn's early multiple use of the term (see Masterman, 1970). Moreover, one of Kuhn's most detailed reassessments of the concept was not published until recently (Kuhn, 1974). However, with the lone exception of the hardback edition by Friedrichs, all of the people herein cited mention Kuhn's (1970a) postscript, his (1970b) article in the Lakatos and Musgrave (1970) reader, Masterman's (1970) article, or some combination of the three. Several merely cite, and then disregard, Kuhn's later works. As was stated above, where Kuhn has attempted to delimit the meanings of his terms, others have tried to extend them.

The above observation indicates that we should look in the direction of the sociologists in order to understand the confusion associated with the paradigm concept. A very important clue that can help us to get started is the longstanding concern among sociologists regarding the *scientific status* of the discipline. This is a concern which dates back at least to

Comte. The idea implies that the standard by which to measure social science is the success of natural science (Douglas, 1972:52-3). This concern has been fueled by Kuhn's simultaneous references to limited rationality and to science. He speaks of science in terms which have long been applied to sociology. With such a parallel, it has required only a small impetus to move some sociologists from seeing their discipline as sharing some elements with natural science to seeing it as being equal to natural science "paradigmatically."

The wish here is father to the thought, for it is only by disregarding Kuhn's warning that the differences between natural and social science communities served to crystallize his thoughts (Kuhn, 1962:x) that one can say, as does Friedrichs,

if one were to apply Kuhn's posture to the behavioral sciences, it would be possible to conceive of the divisive struggle currently being waged within sociology not as *humiliating proof* of the discipline's relative immaturity, but as evidence of its *coming of age*. (Friedrichs, 1970:2, emphasis added)

Friedrichs adds that taking such a stand will allow us to "ignore the *incessant demand* that we profess ourselves worthy of the label 'scientific.'" Such a stance will allow us to keep from "running in embarrassment" when our fundamental differences are pointed out (Friedrichs, 1970:2-3, emphasis added; also see Lachenmeyer, 1971).

Thus, sociologists find paradigms scattered across sociology, but only by corrupting Kuhn's model of science. The discovery of paradigms across the field of sociology have been made possible only by redefining the concept (Heyl, 1975:64-5; Perry, 1977; and Pocock, 1971:14fn.). Analysis, however, requires strict usage of terms. It is only by being strict that we come to understand the dynamics about which Kuhn intends to speak. Emphasis on discipline-wide paradigms must be seen as misplaced:

Paradigms pertain to fields like the study of heat, optics, mechanics, etc.; *there are not and cannot be* paradigms of physics or chemistry. In other words paradigms are not discipline-wide but sub-disciplinary. Their

span is likely to be coterminous with that of specialities; conversely, specialities will be paradigm-bonded social systems (Martins, 1972:19, emphasis added).

If this point is missed, we lose one of Kuhn's most fundamental contributions to discourse on the nature of scientific inquiry.

THE PARADIGMATIC STATUS OF SOCIOLOGY

What, then, is the paradigmatic status of sociology? An attempt to answer that question, especially after a critique of others who have tried the same, may be gratuitous. The important analysis is that of the paradigm concept itself, and of the prospects and limits of its use. Still, the status of sociology in this regard is intrinsically interesting, and such an analysis may help clarify the applicability of the concept.

Perhaps the first point to stress is that the general question as to whether sociology has paradigms at the discipline-wide level is moot; *all* disciplinary groups have paradigms (disciplinary matrices) of this sort (see Kuhn, 1970a:179; 1970b:272fn; and 1974:460fn.). At this level it seems that crisis, or, at least, conflict is inevitable. There is probably no need for a monolithic perspective at this level, and it could be unhealthy were one to emerge (see Merton, 1975:28). Here, a Kuhnian paradigm approach is inapplicable, for no truly extended research can take place at this level. Problems abound, but no real puzzles can be found. To the extent that this *is* sociology, it can be said to be a nonspecialized science (Urry, 1973). If this in essence is sociology, then it certainly does not progress by means of sequential concrete examples.

In this respect, of course, it can be (and is) argued that sociology is different from the natural sciences. If this argument is valid, however, then Kuhn's framework cannot be used to analyze the paradigmatic status of the discipline, and we "nonnatural" scientists should concentrate on doing whatever we are supposed to "nonnaturally." However, the consensus seems to be that sociology is, or will become, a science of the natural vari-

ety. If this position is adhered to, and if we are to use Kuhn's framework, then it is in the substantive areas of sociology that we must look for paradigms (exemplars). If they exist, they will be found in such areas as political socialization, status attainment,² ethnic relations, and so forth, *not* in functionalism, conflict theory, and symbolic interactionism. Those who state so emphatically that there are paradigms in sociology must support their assertions by showing that there is at least one area of research that is guided by concrete examples of scholarship, which serve to generate and to solve puzzles. What we often actually find is research modeled upon no other research at all, upon a short, soon-extinguished line of research or upon a single theorist's speculations. There is little extended puzzle solving. There are few instances in the literature where an important puzzle has been solved. Indeed, there are few puzzles, mostly problems. If a problem is considered important, it is never solved at all, but serves as a point of contention among variant perspectives.³ We find constant

arguing, bickering, and debate, but very little agreement. This lack of agreement affects operationalization and manipulation of concepts, such that different research requires different, often incommensurable data. The concepts themselves seem to change from study to study.

Let us be explicit. Although we see the present situation in sociology as being unsettled, we are *not* arguing that there can be no exemplary research in social science. For example, we feel that in the *substantive* area of attitude change paradigmatic research has long been conducted under the cognitive dissonance school of thought. This school has a strong research tradition. Countless puzzles have been generated and solved within it, and the necessary modeling process apparently has occurred. It should be noted immediately, however, that the schools of sociology are not similar to the school of cognitive dissonance. They are more loosely organized. Very loosely: A greater burden falls on the shoulders of a young sociologist than on those of a physicist. The sociologist is not provided with a set of clear normative guidelines followed by those in a tightly organized group.

The conclusion seems inescapable. If paradigms (exemplars) exist in the discipline of sociology, they are difficult to find. Moreover, if they do exist, they (1) must not be discipline-wide, (2) must be found within substantive areas of research, (3) must have communities of practitioners which coalesce around them, and (4) must be used to both generate and solve puzzles and thus generate a visible research tradition.

REFERENCES

² We should note here the current debate over the theoretical status of status attainment research (see, for example, Horan, 1978). Indeed, two anonymous referees suggested that this research is paradigm-based in the Kuhnian sense. It is not our purpose to enter into this debate in this paper. We do feel that those who seek paradigms in substantive areas such as status attainment are at least looking in the right direction. However, they still must show that the paradigms they find contain *both* the cognitive and the structural characteristics discussed above.

³ Regarding this discussion, it is relevant to note that many analyses of the paradigmatic status of sociology might be seen more accurately as thematic analyses in the sense discussed by Holton (1975). Holton (1975:334) explicitly warns us of the danger of confusing thematic analyses with such things as paradigms and world views. He then quickly notes two major differences between paradigms and themata. First of all, "... thematic oppositions persist during 'normal science,' and themata persist through revolutionary periods" (Holton, 1975:334). The point here is that thematic oppositions (e.g., order vs. conflict) are never resolved in the sense that a puzzle is solved, but are argued over endlessly. A second major difference between paradigms and themata is that "[t]o a much larger degree than ... paradigms ... thematic decisions seem to come more from the individual than from the social surrounding" (Holton, 1975:334). Hence, different individuals using a thematic perspective will slice the sociological pie in numerous ways.

SUBURBAN STATUS EVOLUTION/PERSISTENCE: A STRUCTURAL MODEL*

JOHN M. STAHURA

Purdue University

American Sociological Review 1979, Vol. 44 (December):937-947

A structural model of suburban status change is generated which summarizes and extends previous studies of status persistence. Utilizing a sample of 714 suburbs, I evaluate a causal model of status persistence and compare the results with previous studies. This study shows that 1960 suburban status characteristics, age and population growth exert significant direct effects on 1970 status levels. However, the effects of growth on 1970 status levels, though significant for two of three status characteristics examined, are primarily spurious. This suggests they have a more minor role in the explanation of status change than is suggested by other studies. Additionally, employment specialization, percent black and suburban age are shown to have substantial indirect effects on 1970 status levels while they exert only small direct effects.

The major substantive focus of this study is the specification of a multiple-equation model of suburban status change which summarizes and extends the work of Farley (1964), Guest (1978), Collver and Semyonov (1978), and Stahura (1979). The authors of these studies did not attempt to specify a causal model nor make causal arguments regarding status change. Consequently, their conclusions should be re-examined in light of the results of a causal

analysis where both direct and indirect causes of status persistence are examined. Towards this end a causal model of status persistence/evolution is theoretically explicated and subsequently analyzed. The results are then compared with those of previous studies.

The concept of evolution/persistence has been utilized in urban ecology in several contexts. The first is the literature on the impact of racial invasion-succession on various characteristics (socioeconomic status, etc.) of urban ecological areas. This literature focused on the determination of the potential impact of racial change on the stability (thus persistence and/or evolution) of areal characteristics. Duncan and Duncan's (1957) and Taeuber and Taeuber's (1965) research best typifies this body of literature. In general, it is argued that racial transition has little

I wish to thank Harvey H. Marshall and the anonymous reviewers for their helpful and cogent comments on an earlier draft of this manuscript. Of course, I am responsible for any remaining errors, as well as interpretations of the data. This research was funded by a Purdue Research Foundation Summer Faculty X-L Grant.

impact on the persistence/evolution of areal characteristics. Several reasons for the stability of areal characteristics are given: situational factors, the idea that each area within a metropolis has a persistent functional position in the metropolitan division of labor; and site factors, the idea that, once an area has been developed and its land utilized in a specific pattern to take advantage of the initial site advantages, any change in initial land usage tends to take place slowly.

The most recent utilization of persistence/evolution occurs in the suburban status change literature (Farley, 1964; Guest, 1978; Stahura, 1979; Marshall and Stahura, 1980) in which evolution is operationalized as longitudinal changes in the relative rankings of suburbs on various status measures at two points in time. This literature also demonstrates the persistence of areal characteristics despite the effects of other variables which are likely to influence status change. Additionally, Guest (1978) places suburban status persistence within a historical context in that he demonstrates differences in a pre-World War II model of suburban persistence and a post-war model; post-war persistence is much greater than pre-war persistence.

Collver and Semyonov (1978) have criticized the measurement of evolution employed in these previous studies. They argue that previous methodologies tend to mask evolution that occurs in areal units by dealing only with shifts in status rankings. Collver and Semyonov decompose suburban status change into changes in mean levels, changes in dispersion, and positional change; they then show how each of these components is differentially related to housing, age, population growth, distance from the city center and incorporation. Another important finding is that various status characteristics persist or change to various degrees and that the determinants of change also vary by characteristic.

STRUCTURAL MODEL OF SUBURBAN STATUS CHANGE

Previous studies of suburban status suggest a number of variables that may

affect status change: population growth, suburban age, initial status levels and geographical location. In addition to these, several other suburban variables are hypothesized to be related to status change: percent black, annexation and employment specialization. These variables are causally ordered in a specific fashion as reflected in Figure 1. In the discussion that follows, each subsection provides a rationale for the hypothesized relationships between each endogenous variable represented in Figure 1 and the various factors that are hypothesized to affect them.

Suburban status, 1970. Current status levels (1970) are viewed as primarily a function of earlier status (1960) levels and secondarily of population growth and/or annexation. Three indicators of status are used in this study: percentage of the suburb's population with twelve or more years of education, percentage employed in white-collar jobs, and percentage with incomes of \$10,000 or more (\$15,000 or more in 1970). Studies by Farley (1964), Guest (1978), and Stahura (1979) show that current status levels and earlier status levels are highly correlated, and there are several theoretical reasons to anticipate this relation.

Among the forces which account for the stability of status characteristics, as Duncan and Duncan (1955) point out, is the fact that housing is a durable commodity initially designed for occupancy by a particular income group with certain family size characteristics. Housing modifications are expensive and occur only if there is considerable demand from other groups or if demand on the part of the existing group declines. Both conditions existed in the cores of older central cities where middle-class neighborhoods often found themselves in the path of rapidly expanding immigrant and black populations with very different housing needs. At the same time the middle- and working-class residents of these areas were turning their attention toward suburbia, where transportation changes and government backed financial arrangements made such housing relatively attractive. The result was a considerable conversion of middle-class housing to lower- and working-class use.

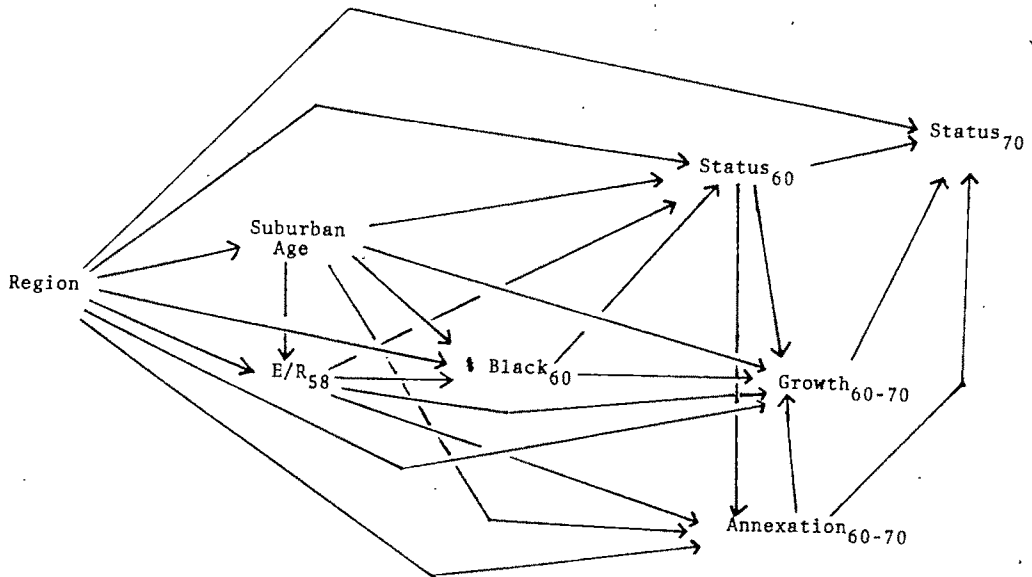

Figure 1. Hypothesized Model of Status Change

Such pressures were not experienced by suburbs in the 1950s and 1960s, creating a context within which considerable stability in the character of land use was possible. Another stabilizing force discussed by the Duncans (1955) is the location of a residential area with reference to job concentrations and amenities; areas located near working-class employment centers, for example, will face high demand from the group as long as the proximity persists.

In addition to these site characteristics, suburbs also play an active role in selecting in-migrants with socioeconomic characteristics consistent with those of the resident population. Control over zoning laws is probably the most efficacious—new housing is typically required to closely resemble existing housing. These laws also often prevent conversion of single family into multifamily dwelling units, thus blocking the influx of low-status persons. A related factor is enforced maintenance of existing homes, which is likely to be vigorous in high-status suburbs, both through formal as well as informal mechanisms. For these reasons very strong effects of 1960 status on 1970 status are anticipated, although these relations are not expected to be perfect since other factors also affect 1970 status.

Population growth between 1960 and 1970 is also expected to be positively related to 1970 status levels (Farley, 1964 and Guest, 1978). Rapidly growing suburbs are primarily adding population due to new housing construction rather than the subdivision of existing units. Thus, the incoming population is moving into new dwelling units which are generally more expensive than existing units of the same type. Consequently, the socioeconomic status of the in-migrant population is likely to be somewhat higher than that of residents, which produces the hypothesized positive relationship between growth and 1970 status characteristics.

Finally, annexation, as measured by the ratio of the 1970 land area to the 1960 land area, may influence current status levels. A suburb can change its overall status through annexation if the status characteristics of the annexed population are significantly different from the suburban population. Despite the obvious advantages of annexing adjacent higher-status residential areas (increased tax base, etc.), lower-status suburbs are assumed to be less successful in annexing such areas because of the greater resistance likely to be encountered. It is assumed that annexed populations will be equivalent or lower in status when compared to the suburb's status level. Consequently, an-

nexation is hypothesized to be negatively related to 1970 status levels.

Population growth, 1960–1970. Population growth (1960 to 1970) is considered to be a function of 1960 suburban status levels, percent black, suburban age and employment specialization (employment/residence ratio, 1958). It is anticipated that the age of a suburb (defined as the number of decades since the first census year it is reported having a population of 10,000) has an independent negative effect on population growth. As a suburb ages, land becomes more intensively utilized which precludes expansive housing or employment development. Thus older suburbs have less potential for population growth as reflected in the lessening availability of land for housing development.¹

Earlier status levels (1960) are also hypothesized to be positively related to population growth. Guest (1978) and Farley (1964) demonstrated that high status suburbs attract disproportionately large shares of suburban-ring populations. Additionally, Schnore (1965) showed that higher status residential suburbs are growing more rapidly than lower status employment suburbs. Consequently, it is reasonable to suspect that status levels influence population growth.

Employment specialization, as measured by the Employment/Residence Ratio, is expected to be negatively related to population growth. It is argued that, as a suburb becomes more specialized as an employment center and an inertia in land use emerges, the potential for population growth is diminished. With the commitment of land to employing activities, less land is available for housing development.

The percentage of a suburb's population which is black is hypothesized to be negatively related to population growth. Marshall and Stahura (1979) demonstrated that percent black is negatively related to white population change in medium and

large suburbs. In small suburbs, percent black interacts with black population growth to retard white growth. However, these negative effects mean a reduction in the rate at which the white population increases rather than indicating a loss of white population. Consequently, the net effect of percent black on total population growth would be to retard growth rather than to induce decline.²

Finally, annexation is hypothesized to be related positively to population growth. The basis for this hypothesis is straightforward—those suburbs that annex land also annex population and consequently will grow more rapidly than nonannexing suburbs.

Annexation, 1960–1970. Annexation is usually treated as a control variable in most ecological research. However, within the context of this model it has substantive importance and is treated as an endogenous variable. Why a suburb annexes adjacent land and what effect annexation has on population growth are important questions which require detailed treatments. The discussion of the determinants of annexation in this study, however, is necessarily limited to the variables included in the model.

There are a number of potential reasons why a suburb annexes—to expand tax revenues, to acquire land for expansion and development, to acquire population, etc. Given the lack of empirical evidence regarding annexation, it is assumed that the suburbs which need to acquire land for development and/or to expand their tax revenues are usually older, lower status suburbs with little industrial or employment concentration. Consequently, annexation is hypothesized to be positively related to suburban age and negatively to 1960 suburban status and employment specialization. In addition, region is hypothesized to be positively related to annexation though the rationale for the relationship is not clearly specifiable. Regional differences in annexation

¹ A more direct measure would perhaps be land use density which unfortunately is not available for many of the suburbs utilized in this study. A population density measure was also considered, but with population and land area change measures in the same model the inclusion of a density measure is statistically and conceptually impractical.

² Marshall and Stahura (1979) also show that black growth has neither an additive nor interactive effect on white growth for a sample of all suburbs. Hence, it is not likely that black growth is related to population growth in this study.

have been demonstrated in the literature and it is possible that they continue to exist given the continuing regional differences in other ecological phenomena such as population growth, black suburbanization, etc. (Klafl and Fuguitt, 1978).

Suburban status, 1960. Previous status levels (1960) are hypothesized to be a function of percent black, 1960, suburban age and employment specialization, 1958. Suburban percent black is hypothesized to be negatively related to 1960 status levels. The basis for this hypothesized relationship is simply that black Americans collectively still occupy an economically disadvantaged status; consequently, they are disproportionately represented in the lower status categories, even in the suburbs (e.g., see Spain et al., 1978). As a result, as suburban percent black increases, the aggregate status level of the suburban population is likely to be depressed.

Schnore (1965) clearly demonstrated the relationship between employment specialization and suburban status. Employment specialization is measured by the employment/residence ratio which is the ratio of the number of jobs in a suburb in 1958 which were in manufacturing, trade and service activities to the number of residents in that suburb employed in these categories. The E/R Ratio directly indicates the degree that a suburb imports or exports workers. Schnore found that residents of employment suburbs are generally lower in status than residents of residential suburbs. Though not explicated by Schnore, it is reasonable to argue that residential and employment activities are somewhat incompatible in that, if given a choice and the economic resources, a resident will choose an environment free from the negative conditions commonly associated with employment activities (e.g., pollution, congestion). Consequently, suburbs with a high degree of employment specialization are likely to have a resident population somewhat lower in status than the population of residential suburbs.

Finally, suburban age is hypothesized to be negatively related to 1960 suburban status. Older suburbs have more houses that, even if sound, are inferior to housing

in newer parts of the metropolis. Older houses tend to be located on smaller lots, require more maintenance and are less likely to have many of the modern conveniences commonly found in newer homes such as central air conditioning. This would lead higher-status persons to seek housing in newer areas thus producing the negative effect of age on suburban status.

Percent black, 1960. Percent black, 1960 is hypothesized to be a function of suburban age, employment specialization and region. The empirical basis for these hypotheses is found in the earlier work of Farley (1970) on black suburbanization. Farley found that blacks tend to be concentrated in older suburbs relatively close to the central city with substantial local employment opportunities. Consequently, I hypothesize that suburban age and employment specialization are positively related to percent black. Another important finding of Farley's (1970) work is a regional pattern of black suburbanization; north central and northeastern suburbs have lower percentage black compositions than suburbs in other regions. Consequently, region is hypothesized to positively affect black composition.

Employment specialization, 1958. Employment specialization as measured by the E/R Ratio is hypothesized to be related to suburban age and geographical region. Older suburbs are more likely to have greater concentrations of employing activities. With time, even high status residential suburbs will experience significant increases in local employment especially in retailing activities. Consequently, suburban age is hypothesized to be positively related to employment specialization.

Given the findings of Schnore (1965) and others that demonstrate regional variations in suburbanization patterns, we have included region in the model of status change primarily as a control variable. Region is operationalized as a dummy variable, where South and West are coded one and Northeast and North Central are coded zero. Consequently, region is hypothesized to be related to suburban employment specialization as well as suburban age, though the nature of the

hypothesized relationships are unclear. It is also possible that region may affect the remaining endogenous variables in the model in a direct fashion, in that region may act as a proxy for other unmeasured variables which may be related to differences in suburbanization patterns.

PROCEDURE

The model of status change that will be employed is a lagged endogenous-variable structural equation model. The model depicted in Figure 1 is an isomorphic representation of the theory of suburban status change explicated in the previous section. In the diagram, single-headed arrows represent a hypothesized unidirectional relationship between the linked variables. Variables within the model are classified as either endogenous (variables not predetermined) or exogenous (predetermined variables). Within the model, both 1960 and 1970 status measures are utilized; the model is a lagged-endogenous variable model which has several distinct properties and advantages in comparison with a multiple regression model. The obvious advantage in utilizing a structural model as compared with the use of a standard multiple regression model is that indirect causal effects can be identified. A less obvious advantage of using a lagged endogenous variable structural model as compared with a standard recursive structural model or a multiple regression model is that the longitudinal nature of some of the data allows for a discussion of several dynamic properties of the model, i.e., the existence of equilibrium states of the dependent variable and patterns of longitudinal change in the dependent variable (Anderson, 1977). However, the examination of the dynamic properties of the suburban change model goes beyond the more modest scope of this research.

The units of analysis are all incorporated places with 10,000 or more population in the 1960 Census of Population located within the boundaries of standard metropolitan statistical areas (SMSAs) that could also be identified in the 1970 census. There were 714 places meeting the above criteria for which all data were available. Data for employment spe-

cialization and percent black are not available for suburbs smaller than 10,000. Consequently, the smaller suburbs and the unincorporated areas could not be used in the analysis. However, a large majority of the suburban fringe population lies in the larger suburbs utilized in this study (about 75%).

FINDINGS: STRUCTURAL MODEL OF STATUS EVOLUTION

The results of the analysis of the status change models (a separate model of change is fitted for each of the three status characteristics) are presented in Table 1. When we consider the model of educational persistence, we find population growth ($\beta = .04$), 1960 educational levels ($\beta = .91$), suburban age ($\beta = -.04$) and region ($\beta = -.08$) have statistically significant ($p \leq .05$) direct effects on 1970 educational levels. It was not anticipated that suburban age would have a significant direct effect on 1970 status levels. However, the magnitude of the effect was not large ($\beta = -.04$) and it will be seen later that the primary effect of age on 1970 educational levels is indirect.

As predicted, 1970 percent white-collar is a function of 1960 percent white-collar ($\beta = .88$) and population growth ($\beta = -.09$). However, suburban age ($\beta = -.08$) again had an unanticipated significant direct effect on 1970 occupational levels. Population growth is negatively related to 1970 occupational levels and not positively as anticipated. The negative relationship between growth and 1970 percent white-collar suggests that suburban migrants in recent years are more heterogeneous with respect to occupations than in previous years. Migrants at all skill levels are now taking up residence in the fringe in response to increasing job decentralization (Dean, 1973; Guest and Cluett, 1974).

Finally, current suburban income levels are found to be a function of 1960 income levels ($\beta = .83$), suburban age ($\beta = -.16$) and region ($\beta = -.09$). Population growth had no significant partial effect on current income levels, contrary to what was anticipated. As a result, the role of popula-

¹ Coefficients reported are statistically significant at the .05 level. These coefficients are reestimates of the model parameters after nonsignificant paths were deleted. Durbin Watson's large sample test (h) for autocorrelation was performed on each of the three equations including lagged variables (Johnston, 1972:312-3). No significant autocorrelations were found.

² Three separate growth equations were estimated, one for each 1960 status measure. In no case was 1960 status related to growth. Growth = population growth 1960 to 1970 using Farley's (1964) growth index.

³ Annex = land area, 1970 divided by 1960 land area in square miles.

⁴ Income, 60 = percent earning \$10,000+, 1960.

⁵ Occupation, 60 = percent white collar, 1960.

⁶ Education, 60 = percent completing 12 or more years schooling, 1960.

⁷ % Black = percent black, 1960.

⁸ E/R Ratio = employment/residence ratio, 1958.

⁹ Age = suburban age.

¹⁰ Region = coded 1 = southern and western suburbs; 0 = other.

¹¹ Income, 70 = percent earning \$15,000+, 1970.

¹² Occupation, 70 = percent white collar, 1970.

¹³ Education, 70 = percent completing 12 or more years schooling, 1970.

tion growth as a key in suburban persistence and/or evolution has to be seriously questioned because in none of the models are the effects large. For income, the effect of growth is not statistically significant ($p \leq .05$); and even where the effects are statistically significant, only for educational levels is the nature of the relationship consistent with the one hypothesized.

Contrary to expectations, annexation exerted no significant direct effect on any of the three status characteristics. This indicates that annexed populations are similar to suburban populations in terms of status characteristics. The only effect annexation has is indirect through population growth and these effects are small (see Table 2). When growth affects status, the mechanism that apparently functions to change status levels is the discrepancy between in-migrants status characteristics and the characteristics of the suburban populations. For educational characteristics, suburban in-migrants are somewhat higher in educational attainment than suburban populations while in-migrants are less likely to occupy white-collar jobs than suburban residents.

In all three status models, the role of region as a control variable becomes evident. For the income and education models, region has significant direct effects on current status levels ($\beta = -.08$ and $-.09$, respectively), i.e., suburbs in the West and South are generally lower in income and educational status than those in the Northeast and North Central regions. These regional differences in suburban statuses are consistent with previous research (Schnore, 1965).

When we consider the direct effects in the remaining equations in the models, suburban growth is shown to be a function of percent black ($\beta = -.13$), employment specialization ($\beta = .07$), age ($\beta = -.25$), region ($\beta = .11$) and annexation ($\beta = .16$) as hypothesized. Of interest is the partial effect of employment specialization on growth. The negative effect of employment specialization on growth was unanticipated. But it is interpretable within the context of recent trends in job suburbanization; suburbs that are specialized as employment centers are apparently at-

tracting migrants who are seeking jobs or wish to live closer to jobs or want better housing. The negative environmental aspects usually associated with employment concentrations are apparently being overridden by economic necessity for an increasing number of suburban migrants. It was somewhat surprising that 1960 educational levels had no significant effect on population growth rates. Apparently, the moderate relationships between earlier status levels and growth rates as demonstrated by Guest (1978) are spurious; the relationship reflects a common set of causally prior variables (age, percent black and E/R Ratio).

Annexation was found to be solely a function of geographical region ($\beta = .16$). Regional differences in annexation exist. Southern and western suburbs are more likely to annex than northern and north eastern suburbs. However, suburban status, age and employment specialization did not have the anticipated effects on annexation. The identification of the determinants of annexation and the explication of the nature of regional differences in annexation remains as a future research goal.

The equations for the three 1960 status characteristics are also presented in Table 1. In each case, 1960 status is a function of percent black, employment specialization and suburban age. In addition, region significantly affects 1960 income levels. The effects of percent black and employment specialization on 1960 status characteristics are of importance since, despite the absence of significant direct effects, significant indirect effects of these variables on 1970 status emerge. In addition to the significant direct effects of age on 1970 status characteristics, the moderate partial effects of suburban age on 1960 characteristics also suggest large indirect effects on 1970 status levels.

The utility of using a multiple equation model becomes apparent when we try to interpret the relative importance of percent black, employment specialization and age in explaining current status levels. Using a single equation model, as was the case in previous research (Guest, 1978; Farley, 1964; Stahura, 1979), would lead to the conclusion that percent black and

employment specialization have no significant effects on 1970 status and that suburban age has a statistically significant but rather small effect on 1970 status. Using a multiple equation model, we see that percent black, employment specialization and age are important determinants of current status levels but that their effects are primarily indirect. The indirect effects of these and other variables on 1970 status characteristics are discussed briefly in the next section.

In Table 2 are presented the decompositions of the effects of each endogenous variable and region on each of the three status characteristics. The decomposition of the effects for 1970 educational levels reveals several interesting findings. The relation between population

growth and 1970 education is shown to be primarily spurious despite the significant direct effect. This pattern persists across the two remaining status characteristics; the relation between population growth and 1970 occupational and income characteristics are also spurious.

The effects of percent black, employment specialization and, especially, age on each of the 1970 status characteristics are shown to be primarily indirect in nature. These three characteristics all operate through 1960 status levels in affecting current status levels. Of particular interest are the indirect effects of suburban age and employment specialization on current educational ($-.32$, $-.06$) occupational ($-.19$, $-.12$) and income levels ($-.20$, $-.05$). These indirect effects will be

¹ Defined as the zero-order correlation coefficients between the independent variables and the 1970 status characteristics. These correlations are standardized regression coefficients and represent the average amount of change in the standard deviation of the dependent variable associated with a standard deviation in an independent variable.

² Defined as the path coefficient, which refers to the amount of change in the independent variable when both are measured in standard deviation units and the effects of all other variables in the particular equation have been controlled (Land, 1969).

³ Defined as the impact of a variable on 1970 status characteristics through other variables in the model. The calculation of this effect is described in Land (1969).

⁴ Defined as that part of the total correlation between an endogenous (independent) variable and 1970 status which is due to common causes (Land, 1969).

⁵ Defined as that part of the total correlation between an exogenous variable and 1970 status due to the correlations of the exogenous variable to other exogenous variables, which in turn are causally related to 1970 status (Land, 1969).

examined in some detail in the discussion section.

DISCUSSION

This study has presented a number of substantive findings of interest to urban ecologists. A causal model of suburban status change/persistence is developed that summarizes and reevaluates the previous research on suburban persistence. In the model, the indirect roles of suburban age, employment specialization and percent black in producing 1970 status levels are explicated. Suburban age, percent black and employment specialization affect current status levels inasmuch as they also affect earlier (1960) status levels. The implications for status persistence suggested by these findings are consistent with Farley's (1964) explanation of suburban socioeconomic persistence. Farley (1964) suggested that the "ecological niche" (the role that a suburb plays in the metropolitan division of labor) determines to a large extent the characteristics of a suburb's initial population composition and also that the persistence of a suburb's functional position insures the replacement of out-migrant populations with in-migrants who are similar in composition. It has also been shown that suburban functional roles persist; once a suburb attains an employing or residential character in relation to other suburbs it tends to remain that way (Stahura, 1978). It appears that suburban age and employment specialization are characteristics that partially define a suburb's position in relation to other suburbs in terms of functional role. What is implied by the findings in this study is that these characteristics serve as indicators of a suburb's initial ecological niche and that these indicators determine to a large extent the characteristics of early suburban populations. These population characteristics tend to persist since a suburb is not likely to change its functional role vis-à-vis other suburbs.

Farley (1964) illustrated his argument using two suburbs (at the time) of the Chicago metropolitan area; Hammond, Indiana and Evanston, Illinois. In its early developmental years, Hammond emerged

as an employment center while Evanston emerged as a residential center. The ecological niches occupied by these two places have persisted and their socioeconomic compositions have changed little in relation to one another; that is, Evanston still has a much higher status level. The role of age in retarding status increase can be demonstrated by making comparisons between Evanston and Hammond to newer employing and residential suburbs. In making such comparisons, it is generally found that newer employing and residential suburbs are higher in status than older suburbs (Stahura, 1975). Once an initial population composition is established as determined by its ecological niche, the composition is likely to persist since functional roles persist.

The supply of resources available within a suburb, the inertia in land use patterns that evolves with development, and types and quality of housing constructed in a suburb's developmental years are all related to the composition of the initial resident population. These ideas are hardly new. They have been articulated by Duncan and Duncan (1955) in their discussion of the persistence of neighborhood housing stocks. The point to be emphasized is that status persistence can be explained by suburban functional role persistence. If any status evolution occurs it is likely due to the effects of age on housing stock and the continuation or discontinuation of certain types of employment activities. Consequently, suburbs that undergo renovation or renewal (i.e., change in land usage patterns) are most likely to change their functional position within the metropolis and their population compositions. As of yet, few suburbs are undergoing renewal in the sense of land use transition but in the near future some evolution in land use is likely to occur as the inner ring suburbs begin to face deteriorating housing stocks and a loss of population and activities to other areas.

The role of population growth in the explanation of status persistence/evolution is overstated in previous research. In this study, growth is shown to have statistically significant effects on 1970 educational and occupational char-

acteristics though the relationship with occupation (negative) was inconsistent with that hypothesized. Population growth had no effect on current income characteristics. The finding that growth differentially affects suburban status characteristics is consistent with the findings of Collver and Semyonov (1978) who show different types of effects to each status characteristic. Guest (1978), however, argues that growth positively influences status change in a significant way. In this study it was shown that, in general, the effect of growth on current status levels is spurious. Consequently, the effect of growth on status change is minor and whatever effect does exist varies in nature according to the status characteristic.

The purpose of this study is to examine the impact of the movement into early adolescence upon the self-esteem of children. Which children are most vulnerable to this role-transition and what is the effect of changes in school environment, pubertal development, and social behavior? With repeated survey interviews and nurses' measurements, 798 school children were followed from sixth into seventh grade in two different types of school systems. Findings indicate that, in seventh grade, white adolescent girls who have entered the new environment of junior high school appear to be at a disadvantage in comparison both to boys in general and to girls who do not have to change schools. Among the girls, the ones with lowest self-esteem appear to be those who have recently experienced multiple changes, that is, who have changed schools, have reached puberty, and who have also started to "date." Among boys, in contrast, early pubertal development is an advantage for self-esteem. These data thus demonstrate the way in which coping with a major role transition can be significantly affected by environmental context, level of biological development, and social behavior.

Adolescence has been characterized as a period of storm and stress compared to childhood (Hall, 1904), particularly in modern societies where this transition period to adulthood is long and the norms that apply are unclear. However, several investigators question the assumption of adolescence as a distressing period for the child. (See Elkin and Westley, 1955; Grinker et al., 1962; Douvan and Adelson, 1966; Offer, 1969; and Weiner, 1970.) The object of this study is to investigate (1) whether the movement from childhood into early adolescence is stressful, specifically in terms of youngsters' self-

esteem, (2) which types of children are most vulnerable in this regard, and (3) what specific impact pubertal development, environmental change, and new social behaviors have upon the self-esteem of early adolescents.

In a cross-sectional survey of 1,918 school children from grades 3-12 in Baltimore, Simmons et al. (1973) did identify early adolescence as an apparently disturbing¹ period for the self-picture of children in general, and of girls in particular (Simmons and F. Rosenberg, 1975), based on their scores on various psychological scales. To be more specific, the largest negative change seemed to occur *among 12 year olds*. Furthermore, according to Simmons et al. (1973), the child's environmental context appeared to have a stronger effect on the self-image than age-maturation. One of the major reasons 12 year olds were more likely than 11 year olds to show an increase in self-image disturbance appeared to be that most 12 year olds had recently entered junior high

Special gratitude is given to Dwight Rowe and the Milwaukee Public School System for their aid in this study.

¹ The term "disturbing" is used here to indicate any change in a direction presumed uncomfortable for the child. It is not meant to connote psychopathology.

school. Twelve year olds in *seventh* grade (and hence in a junior high school) were more likely to show negative self-images than twelve year olds in *sixth* grade (elementary school). There were no comparable differences between 11 and 12 year olds in the sixth grade or between 12 and 13 year olds in seventh grade. Thus, being in a traditional junior high school at the time of puberty appeared to be a significant factor affecting the child's self-image.

In sum, the Baltimore study identified a key developmental year at the beginning of adolescence as disturbing for the self-image, isolated females as being most vulnerable to this disturbance, and suggested that part of the problem was due to a marked change in the child's school environment at that point. While several other quantitative studies support this picture of self-image disturbance in early adolescence (Piers and Harris, 1964; Offer and Howard, 1972) and a greater self-concept disturbance for girls (Offer and Howard, 1972; Bohan, 1973; Hathaway and Monachesi, 1963), other investigations contradict these conclusions (see Long et al., 1968; Rosenberg, 1965; Bohan, 1973; and Maccoby and Jacklin, 1974:chap. 4).² The current study was conducted in order that these relationships could be tested again with a design that would overcome some of the limitations of the prior research.

In particular, there are four major limitations to the Baltimore study. First, similar to much of the prior research in this area, the Baltimore study does not follow the same children over time; it is cross-sectional and therefore the number and type of children negatively affected cannot be determined. In contrast, the current study is longitudinal and follows children through this key period with measures both in sixth grade and again in seventh.

A second limitation of the Baltimore study is that *all* seventh graders were attending junior high school. Thus, they had all recently moved from a protected

elementary school, where they usually had one teacher and one set of classmates, to a new, much larger, more impersonal junior high where their teachers, classmates and even rooms were constantly changing and expectations concerning behavior were markedly different. They had experienced a sharp environmental discontinuity at this key point in the life-cycle (see Benedict, 1954).

Since most other studies have not examined the role played by changes in adolescents' school environment, the question arises as to whether the same disturbance in self-picture would occur in a different type of school, a school in which early adolescents were confronted with less environmental discontinuity. A kindergarten through eighth grade school (K-8) might be expected to present the child moving from sixth to seventh grade with a less sudden change, both in terms of the impersonality of the environment and in terms of others' expectations for adult-like behavior on his part. In order to investigate this possibility, we have compared children moving into traditional junior high schools to children in K-8 schools who are moving from sixth to seventh grade *within the same school*.

This design enables us to explore the question of whether any self-image disturbance that does occur is significantly affected by *environmental context* or whether the result is due mainly to a developmental, *psycho-biological* process such as *puberty*. If the disturbance between sixth and seventh grade occurs regardless of school-type, the explanation will appear to be primarily maturational or developmental. If, instead, an increase in disturbance is more evident in the junior high school with its greater level of social discontinuity, then the change will appear to be heavily environmental or contextual.

We also would like to measure more directly the impact of puberty. The third limitation of the Baltimore research (and of many prior studies) has been the absence of an adequate measure of puberty. The individual's chronological age, which is frequently used, has been shown to be a poor indicator of physical development, particularly for this age group (see Tanner, 1961; 1971; Reynolds and Wines,

² Also see Engel, 1959; Katz and Zigler, 1967; Jorgensen and Howell, 1969 for other quantitative studies.

1948; 1951). In order to improve on this situation, the present study has included other indicators of physical maturation.

Thus, we shall be able to investigate the part puberty plays in challenging children's self-picture in school environments characterized either by continuity or by discontinuity.³ Although past studies do not deal with puberty in different environmental contexts, the literature does suggest that early developing boys generally have an advantage. It is unclear, however, whether early or late maturing girls are better off psychologically (see Clausen, 1975; Faust, 1960; Mussen et al., 1969:613-6).

A final limitation of the Baltimore study is that it contained scanty measures of "dating-like" behavior. Since one of the new major social activities in adolescence involves establishing social relationships with the opposite sex, it would appear important in this current research to investigate the impact of these new relationships on the self-picture for children who have and have not reached puberty in the different school environments. In this way, we can explore whether early dating is stressful or advantageous to the self-picture of different types of children.

In sum, with a key developmental year identified (the transition from sixth to seventh grade), we shall focus on the influence of environmental, biological, and social changes on adolescents' self-esteem. The logic of this paper will be to identify groups at greater risk and to try to specify more and more exactly which subtypes within these groups are most vulnerable in terms of self-esteem. This type of research is consistent with Kohn's (1976) call to investigators to take into account interactions of biological, psychological, and social structural conditions as they affect levels of psychological strain.

METHOD

Sampling

The present study was conducted within the Milwaukee Public Schools from

1974-1976. Seven hundred and ninety-eight school children from 18 elementary schools were followed from grade 6 to 7. These children were interviewed privately by trained survey interviewers, once in sixth grade and a year later in seventh grade. In addition, each student went through several brief sessions with a registered nurse to establish his or her level of physical development.

There were three main populations of schools from which we sampled: (1) eighth grade-top schools (K-8) which involved no change of schools for the child in seventh grade, (2) sixth grade-top schools (K-6) with social characteristics similar to the eighth grade-top schools—in particular, they were predominantly white schools, and (3) the remaining sixth grade-top schools (K-6), which were heavily black and thus not comparable to the K-8 schools.⁴ All seven K-8 schools were asked to participate; only one school refused. A stratified random sample of K-6 schools was chosen from each of the other two categories noted. The stratification variables were the percent of minority students in the school and the size of the school. Altogether there were 18 schools included in the final sample: six K-8 schools, eight comparable K-6 schools, and four predominantly black K-6 schools.⁵

Within the schools sampled, all sixth grade students were invited to participate, which gave every student *within* each stratum of the sample an equal probability of being invited. Parental permission was solicited from all sixth graders in the sampled schools in Milwaukee and was secured from 82% of the original population; 86% of these students remained in the school system for the two years of the longitudinal study.

Two criteria were important in the

⁴ Schools that were heavily Spanish-speaking in composition were excluded for all three populations, due to the unknown validity of our instruments with this ethnic group.

⁵ One of the original comparable K-6 schools refused and a new school was redrawn. Although not pertinent to this article, it should be noted that one original black K-6 school refused as well as one junior high into which black K-6 schools fed. New schools were redrawn.

³ See Seidman, 1960; Smith and Lebo, 1956; Blos, 1962; and Anna Freud, 1958 concerning the role of puberty in the adolescent crisis.

evaluation of the sample design: first, did the sample of schools reflect the population from which they were drawn?⁶ In fact, for each school-type the sample schools are very similar to the population of schools on a variety of variables: median family income, achievement scores, teacher's background, mean percentage of children who move in or out of the school, mean percentage of teachers with only a B.A., mean percentage of teachers with only one year experience (see Blyth, 1977).

A second criterion in the evaluation of the sampling design involved the comparability of the six K-8 schools and the eight predominantly white K-6 schools. It should be noted that the diversity of school-types within the Milwaukee public school system is primarily a function of idiosyncratic historical development rather than a matter of a clear policy difference that could threaten to bias our comparison. However, in order to claim that differences between children in supposedly comparable K-8 and K-6 schools reflect differential reactions, it is necessary to rule out obvious initial differences between the two groups of schools. The data show virtually no differences between the K-8 and comparable K-6 schools on the same wide variety of social characteristics mentioned above (see Blyth, 1977).

This analysis deals only with the white children in the comparable K-6 and K-8 schools since there are not enough black children in these two types of school to allow a separate subgroup analysis and since prior research indicates that black and white children react differently in terms of their self-esteem (Rosenberg and Simmons, 1972; Simmons et al., 1978; Simmons, 1978).

⁶ In order to test such comparability, we investigated whether the randomly drawn sample of K-6 schools within any given stratum of percent minority showed a sample mean more than one standard deviation away from the population mean for that stratum on either of two important characteristics: mean median family income of the area served by the school and the mean percent of under-achievers in the school. The samples involved in the analysis in this paper (that is, the K-8 schools and comparable K-6-Junior High schools) were fine according to this standard.

Measurement

Self-esteem. The major dependent variable used in this analysis is self-esteem. Self-esteem is defined here as an individual's global positive or negative attitude toward him- or herself. In this usage the individual with high self-esteem considers her/himself to be a person of worth, though not necessarily superior to others. Low self-esteem, on the other hand, implies self-rejection, self-dissatisfaction, or self-contempt. Self-esteem is measured here by the same six-item Guttman Scale used in the Baltimore study described earlier (Rosenberg and Simmons, 1972:chap. 2).

Since a key aspect of this study is to replicate the Baltimore research as well as to extend its findings, it was deemed important to use the same exact measure of the major dependent variable. (See Rosenberg and Simmons, 1972 and Simmons, Rosenberg and Rosenberg, 1973 for a discussion of the validity of this scale.) In the present Milwaukee study, the reproducibility is .927, the scalability is .765, the minimum marginal reproducibility is .690 and the percent improvement is .237 as computed by the Ford technique (Ford, 1950). In the Baltimore research, this measure was shown to correlate with the widely used Rosenberg self-esteem scale ($\text{Gamma} = .61$), but to be more appropriate for use with younger children. (See Rosenberg, 1965; Wylie, 1974 and Wells and Maxwell, 1976 for a discussion and highly positive evaluation of the reliability and validity of the Rosenberg self-esteem scale.)

Girls' puberty. In addition to school-type, pubertal development is a major independent variable. For the purposes of this paper we simply distinguish between girls who have begun to menstruate and girls who have not. This information was collected within a few weeks of the survey interview by a nurse who also weighed and measured the children and collected other relevant information.

Menstruation is typically a late sign in the process of pubertal development (Tanner, 1971). In our data, menstruation correlates significantly ($p < .01$) with the following other indicators of puberty for

seventh grade girls: height ($r = .40$), presence of underarm hair (.32), presence of a figure (.55), presence of acne (.41), and nurses' rating of overall physical maturity (.50).⁷ Thus, girls who have begun menstruating are likely to look more developed to themselves, their peers, and adults.

Boys' puberty. For boys, no clear and easy indicator of puberty exists. The best measure of pubertal development, according to Tanner (1971), would involve the measurement of the genitalia. However, it was not possible for us to secure school consent to undress the children; even if such consent could have been obtained, the rate of parental and child refusal would certainly have destroyed the random nature of the sample.

Therefore, we decided to use rate of measured height growth as our main indicator of puberty for boys. In sixth and seventh grade, relatively few boys have entered puberty (Tanner, 1971; Seidman, 1960). Thus we can be fairly certain that boys who are growing very slowly are prepubertal, that is, they have not yet entered the pubertal growth spurt. They are not likely to be at the other end of the spectrum and slowing down their growth as they reach adult height. In contrast, many girls at this age have almost completed their growth in height, and a slow rate of height growth cannot distinguish between early and late developers (Seidman, 1960).

In order to classify boys according to height growth, we utilized norms reported by Stolz and Stolz (1951). Stolz and Stolz followed the height growth of 67 boys through prepubertal, pubertal, and postpubertal periods and reported (p. 106) that the mean gain in height during the pubertal growth spurt was 76.7 millimeters in a year with a standard deviation of 9.18 millimeters and a range of 50.4 to 90.8 millimeters. In our sample, boys were classified as clearly within their pub-

ertal growth spurt if, at the minimum, their height growth was not more than one standard deviation below Stolz' mean. Obviously boys who were growing even faster than this were also classified as pubertal. The range for the rate of growth for these fast growers of 67.72 to 134.63 millimeters the past year encompassed 31% of our sample. At the other extreme, those who grew less than any pubertal boys in Stolz and Stolz' series were termed nonpubertal. These boys' yearly growth ranged from 25.42 millimeters to 49.915 millimeters, and they accounted for 40% of the sample. The middle group which grew 50.4 to 67.593 millimeters a year (29% of the sample) cannot be clearly categorized with these data as either in or not in their pubertal height spurt. (Our mean annual height growth for boys was 61.36 millimeters and the standard deviation was 22.35.)⁸

It should be noted that there is a fairly high correlation between height and pubertal growth ($r = .59$). In order to untangle the impact of actual height and puberty (or rate of height growth for boys), we must control for height when we examine the effects of puberty. However, in terms of numbers of cases, there are very few short boys in our sample who are other than prepubertal, and very few tall boys who are not in a phase of fast growth (see Blyth et al. In press).⁹ Thus, we cannot look at the effects of puberty for tall or short boys separately. In order to control for height, therefore, we include only medium height boys whenever we are inspecting the effects of boys' pubertal development. Among medium height boys, rate of height growth as an indicator of puberty correlates significantly ($p < .05$) with other indicators of puberty: presence of underarm hair ($r = .19$), self-reported rate of muscle growth (.11), degree of

⁷ Although classifications of pubic hair dispersion and breast development have been recommended as indicators of puberty (Tanner, 1971), it is extremely unlikely that either the school system or a sufficiently large random sample of parents or children would agree to our using measures which involved the children's undressing.

⁸ In cross-tabular analysis, this variable is trichotomized; in regression and correlation analysis a dichotomy and effect coding is utilized in which the nonpubertal and the middle group are contrasted to the clearly pubertal boys, in order to make the analysis as comparable as possible to that of the girls.

⁹ Future analyses will examine the impact of height itself and other body features upon self-esteem (see Blyth et al., In press).

voice change (.17), presence of acne (.30), presence of lip hair (.23), nurse's rating of muscular build (.41), and nurse's overall rating of physical maturity (.44).

Early dating behavior. A final major independent variable involves early dating behavior. Early dating behavior was indexed by the following three-item scale: "Do you ever go to dances or parties where there are both boys and girls present? Yes/No" "Do you ever go out with another girl and a couple of boys or meet a group of boys and girls at night? Yes/No" "Do you ever go out with a boy alone? Yes/No." This is a Guttman Scale with a coefficient of reproducibility of .92, a coefficient of scalability of .71, a minimal marginal reproducibility of .72 and a percent improvement of .20.

Measurement of change. In this study, not only is the *absolute* level of the dependent variable of self-esteem of concern, but the extent to which it changes between sixth and seventh grade is also important. We wish to determine whether there are gains or losses in the dependent variable from one year to the next, and whether different subgroups of children vary in the direction or degree of change. It is, of course, possible to compute a simple gain score in which the sixth grade self-esteem score is subtracted from the seventh grade self-esteem score.

However, in considering changes between the two years, it is necessary to control for the initial sixth grade score. Otherwise, in the case of self-esteem, children with initially low self-esteem will have more room for improvement, while children with initially high self-esteem will have more room on the scale to move downward (see Bohrnstedt, 1969). To adjust for these ceiling and floor effects, all analyses use the sixth grade value of the dependent variable (or the "Time 1 Score") as a covariate or control variable while investigating the effect of various independent variables on the raw change score. Thus, an analysis of covariance in a regression framework is used in which the dependent variable is the raw change score, sixth grade self-esteem is the covariate or control variable and the independent variables (such as sex of child and school-type) are "effect coded" and

treated as dummy variables. From this analysis we can derive adjusted mean change scores for subgroups—that is, subgroup change scores that adjust or, in effect, control for sixth grade self-esteem (Schuessler, 1971:209–10). In addition, the regression analysis yields standardized and unstandardized regression coefficients as well as F-tests of significance. The adjusted mean change scores for subgroups can also be derived more expeditiously from the Multiple Classification Analysis program of SPSS. With these methods, we can compare differences among subgroups in terms of direction and magnitude of adjusted mean change in self-esteem; that is, change adjusting for sixth grade self-esteem scores.

An alternate method would be to do an analysis of covariance in regression format that uses the Time 2 or *seventh grade value of self-esteem* as the dependent variable and include in the regression analysis the Time 1 or sixth grade value of self-esteem as well as the independent variables. That is, the dependent variable would be the Time 2 score rather than the raw gain score. In both cases the Time 1 variable would be controlled. We prefer the adjusted mean change scores because this method allows for easier inspection, interpretation, and communication of findings. However, the unstandardized regression coefficients for the independent variables (but not for the covariate) and the significance levels attached to them, as well as tests of significance based on increments in R^2 , remain identical regardless of which dependent variable is used—the change score or the Time 2 score.¹⁰

¹⁰ The identity of these values can be proved algebraically; that is, the use of the adjusted change scores does not double adjust for differences at Time 1 (see Bock, 1975:505). A copy of the proof of this identity can be secured from the senior author (Simmons), as well as more detail about derivation of the change score from either the Multiple Classification Analysis or the regression analysis presented with the figures. In the Multiple Classification Analysis program of SPSS, the adjusted mean for each subgroup is expressed as an adjusted deviation from the Grand Mean Change over all groups. In order to express change for each subgroup in terms of absolute gain or loss, we have added the Grand Mean Change itself to the subgroup deviation from the Grand Mean.

Table 1. Self-Esteem by Sex by School Type (Whites Only)*

Seventh Grade Self-Esteem	K-8 Schools		Comparable Jr. High Schools		Total	
	Males	Females	Males	Females	Males	Females
low	25%	35%	23%	45%	24%	41%
medium	33%	32%	38%	30%	36%	31%
high	42%	33%	39%	25%	40%	28%
	100%	100%	100%	100%	100%	100%
	(111)	(93)	(168)	(148)	(279)	(241)
			$\chi^2 = 17.74$		$\chi^2 = 18.29$	
			$p < .001$		$p < .001$	

*Regression Analysis	B (Standardized)	b (Unstandardized)	Significance p of F	Significance of Increase in R ² when interaction added to equation
2-Independent Variable Equation				
Sex (Male = -1; Female = +1)	-.20	-.69	<.001	
School Type (K-8 = -1; Jr. High = +1)	-.06	-.21	—	
Intercept Constant		3.87		
2-Independent Variables Plus Interaction				p < .05
Sex	-.09	-.31	—	
School-Type	-.02	.80	—	
Sex by School Type	-.16	-.62	.04	
Intercept Constant		3.69		

It should also be noted that analysis of covariance can be performed only when there is no significant interaction of the independent variables and the covariate. All analyses presented in this paper were first tested to make certain this assumption was not violated. In this paper significance levels of $p \leq .10$ are reported and tests for interaction are based on whether inclusion of the interaction term adds significantly to the R^2 .¹¹

FINDINGS

This analysis is focused upon the way in which self-esteem in early adolescence is related to the nature of school environment, to level of pubertal development and to involvement in new kinds of social encounters with the opposite sex. Which types of children appear most vulnerable

at the entry to adolescence? We utilize two approaches in the answer to these questions. First, how do different types of children end up in seventh grade in regard to absolute self-esteem; which children demonstrate more or less favorable attitudes toward the self? Secondly, which children change more in the transition from sixth to seventh grade; that is, which children show greater decrements in self-esteem, which greater increments?

First of all, in this study, as in our earlier work, adolescent girls appear more vulnerable than boys in terms of their absolute self-esteem (see Bush et al., 1977-78; Simmons and Rosenberg, 1975). Table 1 shows that in seventh grade 41% of white girls score low in self-esteem compared to only 24% of white boys ($p < .001$).¹²

¹¹ In any regression analysis presented in the paper, the dependent variable was allowed to vary in its full range but trichotomized for cross-tabular analyses.

¹² The question arises, however, as to whether the relationships between sex and self-esteem might be contaminated by a response-bias often called "social desirability" (Crowne and Marlowe, 1964). This term is used to refer to the possible tendency of certain individuals or subgroups (e.g., females) to

Role of School Environment: Self-Esteem in Junior High vs. K-8 Schools

Does the nature of the school affect the relative adjustment of these boys and girls to the new adolescent role? As indicated above, it could be hypothesized that the greater discontinuity of the move into junior high school could present more self-esteem difficulties for the child than continued attendance at a K-8 school. In Table 1 we see that in both K-8 and junior high schools, seventh grade girls have lower self-esteem than do boys; however, only in junior high school is the difference large enough to reach statistical significance. It should be noted that almost half of the girls who are in a junior high school for seventh grade have what can be considered to be a very low opinion of themselves; they are almost twice as likely as the junior high boys to score low in self-esteem (45% vs. 23%) and they are also more likely to exhibit low self-esteem than girls in the K-8 school-type (45% vs. 35%).

White boys, in contrast, do not appear to be affected by school-type; their self-esteem is about the same whether they are in K-8 schools or junior high schools. This fact, coupled with the lower self-esteem shown by junior high girls when compared to K-8 girls, contributes to the greater discrepancy between the sexes in the junior high schools. As shown in Table 1, there is a difference of 22% between junior high girls and boys, but only a 10% difference in the proportion of girls and boys reporting low self-esteem in K-8 schools.

reply to questions in a way which they feel is socially desirable or acceptable rather than in a manner that expresses their actual ideas and opinions. In other words, children who are generally less willing to admit to socially undesirable thoughts may also be less likely to indicate low evaluations of themselves. In a random half of our seventh grade interviews we included questions designed to assess the extent to which respondents were biased in this way (see Crowne and Marlowe, 1964). However, when a partial correlation is run between sex and self-esteem, controlling for social desirability, the findings change very little over the zero-order correlation. The correlation between sex and self-esteem remains practically the same ($-.17$ and $-.19$); thus, females demonstrate a less favorable self-esteem, even when this control is instituted.

The regression analysis footnoted in Table 1 indicates that there is a significant increment in R^2 when the interaction between sex and school-type is considered above and beyond the additive effects of these two variables ($p < .05$). These results reflect the special vulnerability of girls in junior high schools. That is, girls alone appear to react to the difference in school environment.

Is this vulnerability of the girl a consequence of differential *change* in self-esteem as girls and boys move from sixth to seventh grade in the different types of school? An analysis of the longitudinal data allows us to see whether the noticeable difference in self-esteem among girls in different schools in seventh grade is in some way a result of the fact that girls moving into junior high change their self-picture more than do girls who remain in the same school (the K-8 school). In order to explore this question, as noted above, it is necessary to control or adjust for the student's sixth grade level of self-esteem. Without such a control, it would be impossible to rule out the alternative hypothesis that seventh grade differences are simply reflections of preexisting differences between the children in sixth grade and the concomitant ceiling and floor effects.

Figure 1 is a graph of the mean adjusted change in self-esteem between sixth and seventh grade for boys and girls in each of the school-types, adjusting or controlling for their self-esteem in sixth grade. Comparison of the adjusted mean change scores allows us to see clearly which groups are experiencing relative increments in self-esteem, and which are showing relative decrements. The regression analysis footnoted in Figure 1 uses the simple gain score in self-esteem as the dependent variable, sixth grade self-esteem (essentially the covariate), sex, and school-type as independent variables.

This longitudinal analysis also points to the junior high girl as being at special risk. As Figure 1 clearly indicates, it is the self-esteem of the junior high girls which changes the most. In fact, only *junior high* girls experience an adjusted *mean loss* in self-esteem between sixth and seventh grade. All other groups appear to increase

their level of self-esteem. The regression analysis once again indicates a significant increment in R^2 when the interaction is added to the equation ($p = .06$).

Role of Puberty and Early Dating Behavior for Girls

Puberty. Since boys and girls react

quite differently to the transition into early adolescence, as evidenced by their reaction to their environmental context, the rest of the analysis will focus on each sex separately. First of all, what relationship is there between pubertal development and the self-esteem of girls? Can we further identify those children at greater risk if we take the girls' level of pubertal

Table 2. Self-Esteem in 7th Grade by School-Type and Dating Behavior) White Girls Only)*

development into account? In fact, the data show that in seventh grade pubertal development has little effect on girls' self-esteem in either school-type. While school-type itself significantly affects self-esteem, according to a regression analysis puberty (as measured by the presence of menstruation) has no significant impact.

Early dating behavior. In seventh grade some girls have begun dating-like behavior—that is, they have gone out either singly or in groups with members of the opposite sex. Table 2 shows that dating at this age is detrimental for the self-esteem of the girls.¹³ Fully 34% of girls who are not dating, or dating little, score high in self-esteem compared to only 20% of girls who are dating more ($p < .05$).¹⁴

¹³ Dating is dichotomized so a score of 0-1 is characterized as "Dating Least" and 2-3 as "Dating Most."

¹⁴ It should be noted that we are referring to early dating here. Douvan and Adelson (1966:215-6) also suggest that too early dating has psychological disadvantages. However, in late adolescence Douvan and Adelson (1966) indicate a lower level of adjustment among nondating girls.

In addition, while pubertal development itself has little effect on self-esteem, in combination with level of dating behavior, puberty may be a meaningful factor in increasing vulnerability. As Table 3A shows, early maturing (pubertal) girls who have also begun dating-like behavior are the most likely to indicate low self-esteem: 50% of such girls show low self-esteem in contrast to 36% to 40% of other girls. Moreover, as can be seen in Table 3B, 61% of the early-maturing, dating girls in junior high schools score low in self-esteem compared to 24% to 44% of those in other subgroups. (The regression analysis does not indicate that these effects reach statistical significance, however.)

Thus, these data suggest that girls who demonstrate the lowest self-esteem may be the ones who have experienced change in three major areas earlier than their peers—girls who have reached puberty early, who have embarked early on the new social behavior of dating, and who have experienced a major environmental change by moving into junior high school. Of course, not all of the girls with menstrual periods have reached puberty

in seventh grade and not all of the girls who are dating have started as recently as seventh grade. Some of these changes have occurred earlier. Nevertheless, these girls have assumed a major change in social behavior and have experienced physiological change earlier than many of their peers. They all show less continuity with childhood than do other girls along these multiple fronts.¹⁵

Longitudinal analyses. Again, it is important to ask whether these differences in seventh grade self-esteem are reflective of change between sixth and seventh grade. The question is whether longitudinal analysis will also identify the early-maturing, dating, junior high school girls as particularly vulnerable. As indicated in

Figure 2 (adjusting for sixth grade self-esteem), the different types of girls in *K-8 schools* are more likely to change in a positive direction than are *junior high girls*, with one exception. The exception involves *K-8 girls* who have experienced early life changes in the other two areas and are *both* pubertal and dating. But it is the *junior high, dating, pubertal girls* who demonstrate the most negative self-esteem changes of all; that is, whose mean adjusted self-esteem change scores are the lowest. The regression analysis shows that the school-type and dating-behavior differences reach statistical significance, but the puberty effect and the effects of the 2-way and 3-way interactions do not. Thus, we cannot say with any certainty that the effects here are more than additive and we must be tentative about any joint effects of puberty. Nevertheless, there is suggestive evidence here, to be tested on subsequent samples, that in early adolescence a particularly vulnerable group of children is found among girls who have changed into a sharply discontinuous school environment and who have matured earlier and begun dating sooner than their peers.

¹⁵ An analysis using Jöreskog and van Thillo's (1973) computer program for estimating linear structural equations (LISREL) was attempted in order to indicate the direction of the causal process. Does dating behavior impact on self-esteem more than self-esteem impacts on dating? However, the parameters yielded were not stable but fluctuated, depending on which "instrumental" variables were used in the model. Therefore, we were not able to ascertain causal priorities at this point. Subsequent analysis with three or more waves of data should allow a better test of these effects.

Role of Puberty and Early Dating Behavior for Boys

Puberty. As noted above, the environmental change into junior high did not ap-

pear stressful for the self-esteem of boys although it did for girls. What about the impact of puberty for boys? While early development was, if anything, a disadvantage for the self-esteem of girls, there

is evidence that it is an advantage for boys. As discussed above, the indicator of pubertal maturation for boys is based on their rate of height growth. Controlling for absolute height by focusing on medium height boys, we see that fast-growing or pubertal boys in seventh grade are more likely to demonstrate high self-esteem than are slow-growing or nonpubertal boys (Table 4: 50% vs. 31%). This difference approaches significance only in junior high school and, in fact, disappears in K-8 schools. Thus, while the relationships are not strong, the direction is clear—the effect of early maturation, where such an effect occurs, is an advantage for medium height boys.

Early dating behavior. While early dating behavior is disadvantageous for girls, it has no statistically significant impact on boys. In fact, whatever slight differences there are lie in the direction of dating boys being less likely, not more likely, to score low in self-esteem (19% vs. 28%).

We noted that girls who experienced physiological and social changes earlier than their peers, i.e., were pubertal and dating, seemed to be particularly vulnerable in terms of their self-esteem. There is no such effect for boys. In fact it is the nonpubertal, nondating boy who is most

likely to demonstrate low self-esteem (32% vs. 19% to 22% of other groups). A regression analysis with seventh grade self-esteem as the dependent variable and school-type, pubertal development, and dating behavior as independent variables shows that the effect of puberty approaches significance ($B = .15$, $p = .10$), but that there is no significant effect of school-type or dating behavior and no significant interaction.

Longitudinal analysis. For boys there are too few cases in the various subgroups to compare mean adjusted changes considering school environment, puberty, and dating simultaneously as we did in Figure 2 for girls. Figure 3 therefore depicts mean self-esteem changes (adjusted for sixth grade self-esteem) for each of the combinations of two variables. In Figure 3A, it can be seen that while the self-esteem of pubertal boys rises in seventh grade regardless of school-type, the self-esteem of nonpubertal boys declines again regardless of school-type. Similarly in Figure 3B pubertal boys show a rise in self-esteem and nonpubertal boys a decline irrespective of dating behavior. The regression analysis suggests that puberty has a significant effect on self-esteem but there are no significant effects of dating,

school-type, or of any interaction among the three variables.

Thus, boys and girls react differently to puberty with boys showing a positive self-image response and girls, in combination with other changes, reacting, if at all, in a negative direction. The sexes also react differently to change in the school environment and early dating with boys unaffected and girls responding negatively. What we appear to have is a conditional relationship or an interaction—the children's responses to environmental change, pubertal change and early dating are conditional upon their sex. In order to test for the significance of these conditional relationships or these interactions with sex, we used an additional multiple regression analysis. This analysis indicates not only a significant interaction for sex and school-type but also for sex and puberty. The relevant regression equation used the following logic:

$$\begin{array}{lcl} \text{Change in} & = & a + \text{sixth grade self-esteem} + \text{sex} \\ \text{seventh grade} & & + \text{school-type} + \text{puberty} \\ \text{self-esteem} & & + \text{dating} \\ & & + \text{all possible interactions} \end{array}$$

All 3-way and 4-way interactions could be deleted without a significant decrement in R^2 . However, if the sex and puberty interaction were then dropped, the decrement in R^2 was significant ($F = 5.70$, $df = 1/355$, $p < .02$) or if the sex and school-type interaction were dropped, the decrement in R^2 approached significance ($F = 3.59$, $df = 1/355$, $p = .06$). However, the sex and dating interaction was not significant when we use this test with the .10 level of significance as a cutoff.

DISCUSSION

In summary, these data indicate that boys and girls react quite differently to the transition into early adolescence in terms of their self-esteem. While girls respond more strongly to the sharp environmental discontinuity of junior high school than to the physiological changes of puberty, boys seem to react to pubertal changes but not to those of the school environment. Whereas the self-esteem of girls is af-

fected negatively by multiple changes in environment, physiology, and social relationships, boys, if anything, respond positively at least to pubertal changes.

The net result of these analyses has been to identify, albeit somewhat suggestively, a particularly vulnerable group of early adolescents in seventh grade—that is, white girls who are attending junior high school and who have shown earlier pubertal development and earlier dating behavior than their female peers. In fact, while this article focuses on self-esteem, it should be noted that girls who have changed in these regards indicated greater vulnerability on behavioral measures as well. For example girls who have begun menstruating, that is those who are pubertal, are more likely than other girls to score low on standardized achievement tests (54% vs. 35%, $p < .01$) and to have low Grade Point Averages (GPAs) (28% vs. 18%, $p < .05$); girls who date early are more likely to be the ones to score low in achievement tests (52% vs. 41%), to have low GPAs (31% vs. 16%, $p < .01$), and to rate themselves as causing school behavior problems (38% vs. 16%, $p < .001$).¹⁶

These findings leave several puzzles to be solved. First, why do girls react negatively to major changes of this order while boys, if they respond, respond positively? In particular, why is early pubertal development an advantage for the self-esteem of boys, and, if anything, a disadvantage for girls? (It should be noted that this finding is consistent with prior research which also reports that early development is an advantage for boys but not necessarily for girls—see Mussen et al., 1969; Clausen, 1975; Faust, 1960). Finally, why are the pubertal, dating, junior high girls an especially vulnerable group of youngsters?

¹⁶ In seventh grade a low GPA refers to scores demonstrated by the bottom third of all children in the sample; a lower score on the Iowa Test of Basic Skills (achievement tests) refers to scores obtained by the bottom half of the total sample. In terms of the findings involving dating, the causal direction is unclear. Do early daters therefore have school difficulties or do those with school difficulties turn to dating early? Future analyses will examine such questions (see Jessor, 1977).

Value Systems

At this point, we can only make conjectures concerning the answers to these questions. First of all, part of the answer may lie in the fact that the sexes develop different value systems at this age. According to this reasoning, adolescence frequently entails an increased emphasis on appearance and on popularity with peers. For girls, however, these values placed on sociability and appearance suddenly assume priority while for boys they are still secondary to values established earlier in childhood. Earlier studies of sex-role development give support to this reasoning (see Douvan and Adelson, 1966; F. Rosenberg and Simmons, 1975; Simmons and F. Rosenberg, 1975; Bush et al., 1977-78). In addition, in this sample of seventh graders we find that looks are classified as somewhat more important by girls than by boys¹⁷ ($r = -.10$; $p < .01$), and that the valuation placed on looks has increased relatively more for girls between sixth and seventh grade. (The adjusted mean change score for girls is $+.10$ vs. $-.01$ for boys; $p < .05$. The last finding was based on a comparison of the sexes in terms of mean adjusted change in valuation of looks adjusting for the value placed on looks in the sixth grade.)¹⁸ In addition, the importance placed on popularity with the same sex is higher for girls than for boys in seventh grade ($r = -.20$; $p < .0001$) and has increased more for girls between sixth and seventh grade (adjusted mean change of $+.05$ vs. $-.23$; $p < .01$). Finally, when asked to rank the importance of popularity (being "well-liked"), competence (being "the best in the things you do"), and independence (being "able to do things for yourself") seventh grade

girls were more likely than boys to rank popularity first ($r = .18$; $p = .0001$, looking at the relationship between sex and whether students do or do not rank popularity first).

Thus, there is evidence that, for girls, looks and peer popularity are particularly important elements of their value system and have increased in importance. The difficulty with adopting a new basis for self-evaluation is that one's standing in a new area may be particularly ambiguous. Staking oneself on *others'* opinions of oneself, as peer popularity assumes great importance, would appear to provide the student with an especially unstable reference point, particularly if one is in a new school (a junior high school) where the peers who are evaluating one are less well-known. We are therefore suggesting that since girls place a higher value on popularity than boys, they will feel more vulnerable in junior high. If the girls are engaging in a new, unfamiliar, but important social behavior—e.g., dating—their uncertainty as to how they are doing and their vulnerability will be increased.

Placing high value on *looks* may also place one's self-picture in jeopardy if one's looks are suddenly changing dramatically as in the case of the pubertal girls. For pubertal boys, whose looks are also changing, we are suggesting that looks assume less importance in the total evaluation of the self. Secondly, we propose that the nature of the body-image change is quite different for boys than for girls. Girls develop a figure which makes them look qualitatively different from themselves as children. Boys, on the other hand, primarily become taller and more muscular and athletic-looking, a change less dramatically different and a change in line with previous values placed on athletics and body-strength. In fact, our data indicate that boys place greater value on sports than girls ($r = .28$; $p < .001$), and that pubertal boys are happier than other boys with their muscle development ($r = .15$; $p < .05$) and rate themselves better at sports.

For pubertal boys then, who are becoming more muscular looking, the improvement in their own appearance is probably obvious. In contrast, for pubertal

¹⁷ A series of questions was included asking students how much they valued certain areas, e.g., looks, being liked by peers of the same sex, being good at sports, etc. The questions read "How much do you care about _____? Very much/Pretty much/Not very much/Not at all."

¹⁸ The significance levels for differences between boys and girls in seventh grade are based on the correlations between sex and the value in question. The significance levels reported for changes in values are based on the F-test of the regression coefficient attached to sex in the relevant regression equation.

girls, it may not be clear whether their particular figure development makes them better or worse looking than their peers, many of whom are also developing figures. Their relative standing in looks may have been clearer at an earlier stage when no one had a figure.

In sum, we are suggesting (1) that girls are more likely than boys to use a new set of values to rate themselves and (2) that their standing in these areas is likely to be ambiguous (particularly if their environment, body-type, and social behavior has changed) and, therefore, they are likely to have low self-esteem.

Sexual Pressure

Are there other reasons why pubertal girls react negatively to early dating whereas pubertal boys do not? Why in fact do pubertal girls seem to react more negatively than nonpubertal girls to dating? It is possible that developed girls who have started to date may be under different pressures than less developed girls who are dating. Sexual pressures from their male partners may be more of an issue for the developed than the undeveloped girls and they may find such sexual pressure stressful and challenging for the self-picture. Pubertal boys, of course, would not be expected to be under such external pressure.

While we unfortunately have no measure of sexual activity or of discomfort attached to sexual activity for the total sample, there are two sources of information which seem to lend some indirect support for such a hypothesis. First, we do know whether the girl has a special boyfriend or not and we can surmise that girls with boyfriends are more likely than others to be involved in sexual behavior. The data show that developed (pubertal) girls are more likely than less developed girls to have a boyfriend (46% vs. 33%, $p = .05$). Whatever positive benefits boyfriends may have for the self-esteem of later adolescents (see Douvan and Adelson, 1966:215-6), at this age only 22% of girls with special boyfriends have high self-esteem in contrast to 32% of girls without special boyfriends.

Secondly, in order to obtain more in-

sight into this problem, we conducted in-depth interviews two years later with five ninth-grade junior high girls who, in seventh grade, had shown this combination of low self-esteem, early dating, and early physical maturity. Although there are far too cases to warrant firm conclusions, these exploratory interviews were congruent with the hypothesis that early sexual encounters were stressful for such girls. For example:

First girl:

Interviewer: What about dating, not steady [in seventh grade]?

Girl: Well, I shouldn't of did it. I didn't like it.

Interviewer: Why didn't you like it?

Girl: Because I always thought to myself, "Oh, I'm old enough to go out with a guy." But I wasn't. I didn't know anything. I was stupid.

Interviewer: Well, what kinds of problems were there that you thought you were stupid in terms of handling?

Girl: Well, I don't like a guy trying to touch me and that's what they tried to do.

Second girl:

Interviewer: . . . First of all, were you meeting boys or going out with boys at that age?

Girl: Yeah, I was meeting guys, and then going out roller skating and stuff . . . I'd always go with a group. I find that I do feel more comfortable when I'm with a group . . . My main reason is because, the reason I don't want to be with just one boy is because like I said, I don't know what to talk about. And I'm not the kind who likes to hold hands all the time. I've got to be free, you know? And there's some guy the other night that was wanting me to sit down and I wouldn't. I mean, not me, I mean I'm a happy person, I guess. I feel happy, and the only way I can keep feeling happy that way is if the guy doesn't want to hold my hand, and I don't really like to be kissed, you know.

Interviewer: You feel that's not where the boys are? They do want to hold hands and kiss you?

Girl: Yeah. That's what happened

when, like I told you, [I went out with] my brother and his girlfriend [and a guy] and, well, they were kissing up in front, and he wanted to; I didn't. So I faked sleeping which I shouldn't of did cause he caught me.

Thus, while we cannot answer all the questions these data raise, it is likely that part of the answer to these questions lies in the different value systems emerging in adolescence between the sexes and the differences in heterosexual treatment of the more vulnerable pubertal, dating girls (girls whose physical maturity is in advance of their emotional maturity).¹⁹

CONCLUSION

The life-course necessarily presents individuals with several major role-transitions, some of which coincide with periods of significant physiological change. The movement into early adolescence is one such role-transition; and in our earlier studies of children from age 8 to 18, early adolescence was identified as a particularly stressful time for one key aspect of mental health—that is, for the self-image. The current study has continued to explore the impact of this role-transition for self-esteem with the aim of further specifying the types of children who are most vulnerable. With repeated survey interviews, seven-hundred and ninety-eight school children were followed from sixth to seventh grade.

The main findings from this study document the importance of social structure and social context for mental health. That is, in terms of their self-esteem, white adolescent girls who have entered the new environment of junior high school are at a clear disadvantage in comparison

both to boys in general and also to those girls who do not have to change schools in seventh grade. When the entrance into adolescence is sudden and discontinuous (see Benedict, 1954), girls appear to have more difficulty in adjustment. The clearest finding of this study, then, is that girls who have entered junior high school are at greater risk for negative self-esteem than are other types of children. In addition, the data suggest that this risk is further increased for girls who have experienced other major life-changes early (changes which their peers have yet to undergo)—e.g., those girls who have not only experienced the *environmental* discontinuity of junior high school, but also the early *physiological* transformations of puberty and the new *social* behavior of dating. According to the data, one reason for the differential reaction of girls and boys to these environmental and other changes may be that, in early adolescence, girls' values are shifting more fundamentally than are those of boys.

Whether the vulnerability evidenced by these early adolescent girls is merely a temporary reaction to the difficulty of coping with multiple, simultaneous changes or whether these same girls will remain at risk in later years is a question that can be answered only by future research. To many developmental theorists (Erikson, 1968; Levinson, 1977), certain periods of personal turmoil are beneficial to long-term adjustment because they allow a more thorough exploration of alternatives for the self as well as for a higher level of re-integration. Without such a re-integration, the problems posed by future life-stages may become more difficult to handle and mental health may become more problematic. Thus, in this view, early adolescent turmoil is important for the self-picture and for adjustment in the next stages of life. However, a contrary view holds that many individuals are weakened by stress and thereby become less capable of dealing with the subsequent life-challenges (see Anthony, 1969). The long-run impact of self-esteem disturbance at the point of transition from childhood into adolescence remains to be investigated. In the meanwhile, the current data emphasize the importance of en-

¹⁹ It is possible that girls who date early and find such dating stressful in early adolescence, may nevertheless find their experience an advantage in late adolescence. At this early age, however, there is no delayed advantage to the self-esteem from dating experience. That is, girls who have begun dating in sixth grade, and continued to date, have no higher self-esteem a year later in seventh grade than girls who have started to date in seventh grade. Both of these groups of early daters have lower self-esteem than girls who have never dated.

vironmental context to the individual's ability to cope with a major role-transition.

TEMPORAL CHANGES IN WORK CONTENT*

KENNETH I. SPENNER

Center for the Study of Youth Development, Boys Town

American Sociological Review 1979, Vol. 44 (December):968-975

Hypotheses about temporal changes in work content over the past century include notions of the upgrading, downgrading, and no-change in skill requirements over time. Current evidence is limited largely to case studies. Analytically, two types of change underlie aggregate variations in skill requirements: change in the distribution of workers in jobs and actual change in the content of jobs. Recent research for the first type of change in the American economy suggests a modest skill downgrading since 1900. Using data from two consecutive editions of the *Dictionary of Occupational Titles* for a sample of jobs, I present new evidence that shows small variations for the second type of change for the last 10-12 years. There has been a slight upgrading in skill requirements in several sectors of the labor force.

Three arguments have been made about the temporal continuity of work quality in recent history.

The conventional *upgrading* thesis suggests the effects of technological change and, more generally, the effects of industrialization increase the aggregate level and range of skills in the occupational structure (Kerr et al., 1960). The main mechanisms include the increased complexity of work in high technology fields and the increased interdependence of work. Workers experience less supervision and routinization as a function of improvements due to automation.¹ The steady increase in educational credentials in recent years is often used to support the upgrading hypothesis, but this type of evidence is not without limitations (Braverman, 1974:424-9).

According to the *downgrading* hypothesis, the quality of work—assessed by the required levels of skill, training, complexity, and autonomy—has decreased over

the course of this century. Rather than viewing technology as an autonomous force that eliminates routinized work, technology is viewed as an instrument of capitalist production. The logic of capitalism, through devices such as scientific management, numerical control, and the redesign of jobs, lowers the value of labor and dilutes forms of knowledge and skills, such as might be found in craft occupations. The result is a growing mass of unskilled and semiskilled workers, particularly in lower white-collar or clerical fields. Braverman (1974; also, see Bright, 1958; 1966) provides a rich argument in this vein, and marshals an array of supporting case-study evidence.

Finally, there are those who argue there has been very little or no change in the aggregate skill requirements of work (Horowitz and Herrenstadt, 1966). One version of the *no-change* hypothesis suggests that some sectors of the occupational structure have experienced upgrading, others downgrading, and the net change is likely small (Hall, 1975:314-55).

In sum, there are three hypotheses about temporal changes in work content. The arguments are extensive, and with one or two exceptions, a large body of case studies (of select industries or jobs for a single firm or area, for a brief period of history) has been used to support one or more of the positions. No attempt has been made to judge this voluminous body of literature. A fair conclusion is difficult to achieve owing to issues of inclusiveness, noncomparability, and variations in temporal, geographic and population

¹ Further information on this position and the larger debate can be found in: *Work in America* (Report to the Secretary of HEW, 1973), *Technology and Work*, (Harvard University Program on Technology and Society, 1969), or *The Employment Impact of Technological Change* (National Commission on Technology, Automation and Economic Progress, 1966).

coverage. These limitations are outlined later.

METHODOLOGICAL ISSUES: NEW EVIDENCE FOR TYPES OF CHANGE

Aggregate variations in the content of work can be generated by two different types of change. First, the overall level of skill required in the economy can vary as a function of changes in the marginal distribution of workers to jobs. For example, an influx of workers into routinized clerical jobs would decrease overall skill levels as more workers are exposed to a lower average level of complex work. This type of effect could operate independently of the second type of change, which is an actual change in the content of jobs apart from the numbers of workers in them. The forces generating within-job change may be empirically quite different from the forces that change the marginal distributions. Moreover, singular judgment on the validity of upgrading, downgrading, and no-change hypotheses is inappropriate as the types of change may operate in opposite directions. There is some indication that this may be the case.

In a recent paper, Dubnoff (1978) reports on interoccupational shifts and changes in the quality of work in the American economy from 1900 to 1970. Using temporally constant measures of work content (U.S. Department of Labor, 1965) Dubnoff assesses decennial changes in the distribution of workers to levels of complexity using indicators for work involvement with data, people, and things. The method assumes temporally constant work content for job categories and, therefore, measures only the first type of marginal change. For the total labor force, Dubnoff finds evidence of a steady downgrading for level of involvement with data. The change is largely at the expense of females in the nonmanual sector of the labor force. Level of involvement with people shows very little overall change, but females in the nonmanual sector experience a sharp downgrading of interpersonal complexity of work as a function of their changing or new-found occupational locations. Finally, complexity of involvement with things shows a modest

downgrading in the aggregate over the 70-year period. Work with things shows an upgrading for both gender groups in the nonmanual sector and a downgrading for both groups in the manual sector. Again, these patterns reflect only changes in the distribution of workers to jobs, not changes in job content. In sum, there is support for Braverman's argument using changes in marginal distributions, although most of the downward shifts are due to movements out of farming and growth of the female dominated clerical sector. Other sector-gender comparisons show stability or slight upward shifts in skill requirements.

Change in the actual content of work is more difficult to assess. It requires independent, multiple point in time measures of criterion variables for a large sample of jobs in the American economy.² The complexity of the comparison is compounded by issues of appropriate criterion variables and the comparability of job classification systems. Only one study could be located that has some of the requisite features. Horowitz and Herrenstadt (1966) draw upon a selective sample of jobs from several industries from the 2nd (1949) and 3rd (1965) editions of the *Dictionary of Occupational Titles* (DOT). Their study uses a number of work characteristics that were scored for DOT jobs in each edition. Three production industries (slaughtering and meat packing, rubber tires and tubes, and machine shop trades) and two service industries (medical services and banking) were the subject of investigation for the 15-year period between DOT editions. Horowitz and Herrenstadt conclude that there has been very little, if any, consequential change in overall skill levels for the period under study (mid-1940s to early 1960s).³

² Among the indicators for the skill requirements or content of work are: complexity, autonomy, routinization, closeness of supervision, levels of involvement with data, people, and things, authority, control over the pace of work, physical demands of work, and working conditions.

³ Of this study, Braverman (1974:213) writes:

It is an attempt to assess "worker characteristics required of the changing jobs" entirely on the basis of the descriptions of "job content" in the . . . *Dictionary of Occupation Titles*. . . . A more arid and unrewarding exercise can hardly be

While limited in time and criterion variables, the Horowitz and Herrenstadt (1966) study is noteworthy in its rigor and in its attempt to include more than a single industry or occupation. Additionally, it provides an assessment of change in work content net of the marginal distributions of workers in jobs.

CONCEPT AND METHOD OF A NEW COMPARISON

By level of skill I mean the degree of mental, interpersonal, and manipulative complexity inherent in a job. The skill levels of jobs in industrial societies provide differential remuneration and occupational rewards, and vary in the required kinds of credentials, experience and training that permit holding the job (see Bright, 1966, for a related typology). Over time, the level of complexity inherent in work likely changes due to larger sociological processes such as automation and technical change, and the instrumental devices of capitalist production such as scientific management, numerical control and the redesign of jobs.

With the recent release of the 4th edition of the DOT (1977), it is possible to extend the earlier study by Horowitz and Herrenstadt to include a larger portion of the labor force and a more recent time period. The extension is important for two reasons. First, it brings the time period covered by empirical evidence a step closer to the scope of the hypotheses. Second, while the data are admittedly limited, they are the only available data with which to assess actual changes in the content of work, net of the distribution of workers for the entire United States economy.

imagined, and the result is that after scores of pages of meticulous tabulations and statistics, the authors conclude that "the overall net change in the skill requirements during these fifteen years was 'remarkably small.'"

"Arid" and "unrewarding" do not constitute sufficient grounds for dismissing the study. It is an oversimplification to say the ratings are "entirely on the basis of the descriptions of 'job content,'" owing to the over 75,000 field validations of the ratings. The issue is not so much the basis of the ratings, as it is their (largely unknown) accuracy (see Spenner, 1980).

The 3rd edition of the DOT contains about 13,800 uniquely defined titles. Each job was scored by occupational analysts at the Department of Labor on levels of involvement with data, people, and things. The scale values and definitions appear in the Appendix. These scores were validated against *in situ* samplings of the more populous 4,000-5,000 jobs. The variables are taken here as indicators of levels of complexity of work with the three functional foci.⁴

The 4th edition of the DOT (1977) added over 2,000 job definitions, and some 3,500 others were deleted from the 3rd edition. All titles, definitions, and ratings were checked and updated in onsite job evaluations conducted by the Department of Labor.⁵ The major changes between the two editions include the addition, deletion, and adjustment of titles to reflect changes in the occupational structure, and the removal of all gender-specific language in job definitions (e.g., virtually all 3rd edition "foremen" job titles are now "supervisors").

To obtain population estimates of the complexity variables, a 5% (N = 622) random sample of 4th edition titles was drawn. Note that the sample is of jobs in the American economy and not a sample

⁴ These three variables are a limited sampling of skill requirements, and more broadly of work content (see the variables listed in fn. 2). I would expect that the three variables are necessary, but not sufficient or inclusive indicators of the skill content of work. The levels of data, people and things scored for each job refer to the "highest appropriate function in each hierarchy to which the job requires the worker to have a *significant* relationship" (Department of Labor, 1966:649). The measures are more precise than the "highest" level used but probably not as accurate as the "most prevalent" function required on a day-to-day basis. While the DOT was originally designed as an aid to employment agencies, initial evidence on reliability and validity shows that DOT variables may prove quite workable for social research. Evaluative measurement information can be found in Spenner (1977; 1980; also see Kohn, 1969; and Temme, 1975). The comprehensiveness, national scope and multiple time point evaluations of the DOT should be weighted against measurement issues of reliability and validity.

⁵ In theory, the 3rd and 4th editions of the DOT represent completely independent evaluations of jobs. This is probably not the case. Some 3rd edition jobs were checked for accuracy, some fraction were likely unchecked and many others received an independent evaluation.

of individuals in the labor force (see Dubnoff 1978, for evidence on the latter). The sample of jobs purposely is not weighted in order to isolate changes in job content from the number of workers in jobs. Each title (definition) was matched to its 3rd edition equivalent. Each sampled title was also assigned to one of three groups on the basis of the quality of the match between editions: (1) "exact match" (word-for-word congruence between editions; $N = 466$, 75% of total); (2) "approximate match" (two definitions having a clear majority of their verbal content in word-for-word agreement, but with one definition slightly more or less inclusive than the other; $N = 77$, 12% of total); and (3) "no match" (new titles in the 4th edition without analog in the 3rd [including military titles] or instances of a poor match between 3rd edition options for a 4th edition code; $N = 79$; 13% of total).⁶

Table 1 provides the means for levels of work with data, people and things for matched titles. The upper panel shows overall means and standard deviations by match quality; the lower panel reports means for DOT major occupation groups.⁷

A comparison of means and variances for edition-specific variables by exact and approximate match quality shows only one marginally significant difference. In the 3rd edition, level of involvement with things is somewhat higher ($p = .051$) for exact match jobs compared with approx-

imate matches. The null hypothesis of no difference by match quality cannot be rejected in all other comparisons. Hence, the quality of job match between editions will not affect the inferences. In the remainder of this report, the two groups are combined ($N = 543$).

The major trend in the table shows that the levels of work with data, people and things have become more complex over the last ten to 15 years. I have avoided, and the reader is cautioned against, treating the same score across scales as equivalent. In this paper the measures are treated separately. Taken as three separate comparisons, in each case the level of complexity is slightly upgraded *and* the number of jobs upgraded exceeds the number that were downgraded. These changes represent from 1/7 to 1/4 of a standard deviation in the respective distributions.

Repeated measures analysis of variance can be used to detect mean differences on a trial factor (3rd-4th editions) and to show the labor force sector location of the change on a categorical factor (DOT major occupation group). Overall mean differences in complexity levels are significant well beyond conventional levels (for data, $F_{1,534} = 26.99$, $p < .001$; for people, $F_{1,534} = 83.47$, $p < .001$; for things, $F_{1,534} = 32.98$, $p < .001$). Comparison of no match titles in the 4th edition (which largely reflects new jobs in occupational structures) with matched titles shows no change for work with things, a small upgrading for work with data (not significant), and a significant upgrading for work with people ($p = .038$). In contrast to much of the popular speculation on the topic, new jobs in the economy during this period show no massive overall upgrading in these skill requirements compared with existing jobs, particularly for work with data and things.

In the lower panel in Table 1, the main effect for rows or DOT major occupation groups is significant since there is substantial variation in the levels of involvement by sector of the labor force. The trial factor by categorical factor interaction, interpreted as differential change in the level of complex work by sector of the labor force, is not significant ($p = .145$) for

⁶ All titles were coded twice under blind conditions. Intercode agreement on the DOT code and match quality code was 99% for titles eventually designated as exact matches. Intercode agreement on titles eventually designated as approximate and no match was 87%. In virtually all cases, the disagreement was resolved in locating an exact or approximate match for a title designated no match by one coder. One coder had substantially more DOT coding experience that proved the difference. An analysis check shows the distribution of match quality is random across aggregations of DOT jobs (i.e., by DOT major occupation groups, $F_{8,534} = 1.13$, $p = .338$).

⁷ In the 4th edition of the DOT the No Significant Relationship levels for each variable were eliminated on the grounds that all jobs have at least a minimum level of activity with respect to each of the functional foci. To afford metric comparability between editions, for data, 7's and 8's were recoded to 6's (Comparing), for people, 8's were left unchanged as this level was relabeled to Taking Instructions-Helping, and for things, 8's were recoded to 7's (Handling).

Table 1. Means for Third and Fourth Edition Level of Work with Data, People, and Things (by Match Quality and DOT Major Occupation Group)

A. Overall Comparisons	N	3rd Edition ¹		4th Edition	
		\bar{x}	s.d.	\bar{x}	s.d.

¹ All differences between 3rd-4th edition means are significant at $p < .001$.

² Only for 3rd edition Things is difference between exact and approximate match significant at $p = .051$.

* Difference between paired means significant at $p < .05$.

** Difference between paired means significant at $p < .01$.

† Difference between paired means significant at $p < .05$ under F adjusted for all comparisons (Sheffé procedure).

people, and is significant at conventional levels for data and things, but is small in size in each case.

An inspection of paired mean comparisons clarifies the overall effects. On the one hand, the upgrading in level of involvement with people is uniform across sectors. On the other hand, the upgrading for involvement with data is specific to service, machine trades, and miscellaneous jobs, which are a minority of the labor force. For level of work with things, the change occurs largely in professional, technical, managerial, clerical, sales, processing, and miscellaneous jobs. If the much more conservative Sheffé procedure is used (see Winer, 1971:170-204, 514-32), which controls the overall likelihood of Type I error across all comparisons, there are a few remaining significant differences. But given the limits of this test, the evidence is uniform and clear: there is no evidence for the mean

downgrading of the skill requirements of work. Rather, the data for the time period under consideration show no change or, if any, a slight upgrading in levels of involvement with data, people, and things. I would hesitate to choose between the no-change and upgrading hypotheses, other than to note that, on balance, the upgrading receives more support than the no-change hypothesis.

There are several threats to the validity of this conclusion, even for the limited time period in question. First, the scales of measurement may be distorted and do not reflect interval or ordinal properties (Scoville, 1972). Yet these scales do correlate well with other variables often taken as indicators of the skill content of work, including General Educational Development, Specific Vocational Preparation, substantive complexity, levels of routinization and closeness of supervision (Spencer, 1980). Additionally, the

analysis was redone with the original skill levels collapsed to a dichotomy. The conclusions do not change; the net upgrading exceeds downgrading (people and things) or there is no appreciable change (data).

Second, suppose the three variables contain various forms of random measurement error. While this possibility cannot be ruled out, since the measurement properties of DOT variables are largely unknown (see Spenner, 1980, for some initial evidence), estimates of means are unbiased with respect to random measurement error.

Third, mean differences may be due to changes in the coding procedures between the 3rd and 4th editions. For example, the elimination of no relationship categories in the 4th edition might result in jobs coded in these categories in the 3rd edition being disproportionately upgraded in the new edition. When jobs coded no relationship in the 3rd edition are removed from the analysis, the evidence for data and people deteriorates (to show no net change). For involvement with things, the evidence becomes slightly stronger in favor of the upgrading hypothesis. Thus, the upgrading in data and people in Table 1 reflects either (a) the change in coding procedures between editions, or (b) true upgrading that disproportionately occurs in jobs coded no relationship in the 3rd edition. Present data do not permit choosing between these two options. But the original conclusion of no-change or slight upgrading across the three skill arenas remains unchanged.

Finally, suppose the DOT analysts implicitly harbored an upgrading hypothesis and nonrandomly upgraded a large number of jobs. The hypothesis cannot be ruled out on the basis of evidence in hand. However, a massive bias of this sort is difficult to imagine due to the large number of analysts spread across multiple field centers in all parts of the country. Moreover, if such a bias is operating to any appreciable extent, then it should involve a modest number of DOT jobs that show at least a one-scale point upgrading in scores between editions. To the contrary, the vast majority of sample jobs are unchanged in data, people and things scores between the editions (81, 77, and

87%, respectively). In fact, 2-4% of sample jobs showed downgrading on one of the dimensions.

DISCUSSION

Hypotheses about changes in the content of work for the American economy have been the subject of substantial debate in recent years. Each of the traditions has marshaled a rich body of case studies in its support (Braverman, 1974; Report to the Secretary of HEW, 1973).

Analytically, two types of change underlie overall aggregate variations in skill levels: change due to variations in the marginal distribution of workers to jobs, and change due to true variation in the work content of jobs. Recent evidence (Dubnoff, 1978) suggests changes in the distribution of workers to jobs, including sector specific growth in the labor force, have resulted in a modest net downgrading of skill requirements since 1900. Evidence presented here, in conjunction with one of the more inclusive studies of the past, suggests very little change, if any a slight upgrading, in the actual skill content of work over the last quarter century.

But the test of the hypotheses for the latter type of change is a weak test rather than a strong test. The limitations are not those of ideas or method but are limitations of available data for the entire labor force over a long period of time. Only a limited part of the conceptual domain of skill requirements, levels of work involvement with data, people, and things, for a short span of history (the last 10-12 years), was examined. Rather than being definitive, the outcomes reported here are best viewed as but one piece of a much larger puzzle of evidence. More precise choice among the alternate hypotheses requires an expanded design with multiple indicators for skill content independently assessed for a large sample of jobs at regular intervals over 30-, 40- or 50-year periods.

In sum, the comparison of consecutive editions of the DOT provides a piece of evidence to further inform an ongoing debate. The issue is complex both in concept and measure. If the DOT is used and is assumed valid then this type of evidence

for recent years shows no support for the downgrading hypothesis. The potential problems with using the DOT for research purposes, such as its unknown reliability and validity, have been mentioned; but the DOT is what is currently available and it seems better to use it carefully than not to use it.

APPENDIX

RELATIONSHIPS TO DATA, PEOPLE AND THINGS
(U.S. Department of Labor, 1965:649-50; 1977:1369-71)

Data refers to "information, knowledge and conceptions related to data, people or things, obtained by observation, investigation, interpretation, visualization, mental creation; incapable of being touched; written data take the form of numbers, words, symbols; other data are ideas, concepts, oral verbalization."

People refers to "human beings; also animals dealt with on an individual basis as if they were human."

Things refers to "inanimate objects as distinguished from human beings; substances or materials; machines, tools, equipment; products. A thing is tangible and has shape, form, and other physical characteristics."

Data	People	Things
0 Synthesizing	0 Mentoring	0 Setting up
1 Coordinating	1 Negotiating	1 Precision working
2 Analyzing	2 Instructing	2 Operating-Controlling
3 Compiling	3 Supervising	3 Driving-Operating
4 Computing	4 Diverting	4 Manipulating
5 Copying	5 Persuading	5 Tending
6 Comparing	6 Speaking-Signaling	6 Feeding-Offbearing
7 No Significant Relationship	7 Serving	7 Handling
8 No Significant Relationship	8 No Significant Relationship	8 No Significant Relationship

In the 4th edition, level 6 (Comparing) is the lowest for Data, level 8 (renamed "Taking Instructions-Helping") is the lowest for People, and level 7 (Handling) the lowest for Things. All other definitions are intact between editions. Detailed definitions of each level for each dimension can be found in either edition of the *Dictionary*.

WHITE MOVEMENT TO THE SUBURBS: A COMPARISON OF EXPLANATIONS*

HARVEY MARSHALL

Purdue University

American Sociological Review 1979, Vol. 44 (December):975-994

In this study the causes of two aspects of white movement to the suburbs are analyzed: the probability that a white central city resident moved to the suburbs between 1965 and 1970, and the probability that a white in-migrant to metropolitan areas settled in the suburbs. The units of analyses are the 112 metropolitan areas where the central city had a 1960 population of 100,000 or more, and where the central city and the metropolitan area were not coterminous. Primary concern is with determining whether whites were "fleeing" central city problems (such as crime, taxes, strikes, race riots, and large black populations) or were drawn to the suburbs because it is there that new housing and jobs were located. A model of the suburbanization process is explicated and evaluated, using path analysis.

INTRODUCTION

In this paper some of the causes of white population movement to the suburbs are examined. The major goal is synthesis of two hitherto distinct explanatory frameworks: (1) that whites are "fleeing" central cities of large metropolitan areas to avoid a variety of perceived problems, such as civil disorder and high crime rates; (2) that suburbanization reflects white response to characteristics of the spatial structure of met-

ropolitan areas, especially the redistribution of jobs and housing between cities and their suburbs. A model of population suburbanization is specified and evaluated which includes variables from both frameworks. This model provides insight into the underlying dynamics of the process and the importance of different types of variables in relation to one another, as well as the extent to which observed correlations are spurious. For example, while the movement of whites to suburbs is more rapid in metropolitan areas where the central city's crime rates are high or where there have been a number of race riots, it is not clear what portion of these relations are causal or their importance relative to one another.

Two aspects of the redistribution phenomena are analyzed. The first is the probability that white central city residents moved to the suburbs of their metropolitan areas between 1965 and 1970.

Research supported by Grant RO1-MH28815-01 from the Center for the Study of Metropolitan Problems, NIMH. I would like to thank Jeff Dunlap and Gaye Matthews for assistance in preparation of the data. John Stahura and Martin Patchen also provided invaluable comments on earlier drafts, as did three anonymous reviewers. Of course, I alone am responsible for any remaining ambiguities or errors.

The second is the probability that white in-migrants to metropolitan areas settled in the suburbs rather than the central city during that interval. Of course, these are only two of the components of the overall process of white suburbanization: the more rapid growth of white population outside of central cities. Other aspects are differential mortality and fertility between central cities and their rings, as well as the size of the counterstream from the suburbs to the cities relative to the opposite stream.

A full understanding of the entire process will require separate study of all aspects. Nonetheless, important points of departure are the analysis of movement from cities to suburbs as well as the distribution of in-migrants between central cities and suburbs. These are major components in the complex of factors that are responsible for the more rapid growth of suburban compared with central city populations. Each is conceptually distinct, and consequently may be affected by different variables, or by the same variables in different ways. The units of analysis are Standard Metropolitan Statistical Areas (SMSAs) defined by the Census Bureau in 1960 and 1970, with 1960 central city populations of 100,000 or greater, with exceptions described more fully later.

The study has numerous theoretical and policy implications. The loss of white population has long been regarded as a basic source of the problems experienced by central cities. There appears to be widespread acceptance of the hypotheses that the primary motives of whites locating in suburbs is avoidance of blacks, crime, and civil disorder, yet there has been no attempt to specify a general framework interrelating these variables, either with one another or with structural characteristics of metropolitan areas. In particular, no previous work has systematically examined the hypothesis that the various dimensions of civil disorder may be differently related to white suburbanization, as well as causally connected with crime, black population size, and the structural characteristics. Instead, emphasis within sociology has been on the role of the structural characteristics (e.g.,

Bogue and Harris, 1954; Bradford and Kelejian, 1973; Kain and Niedercorn, 1975; Olsen and Guest, 1977).

THEORY AND HYPOTHESES

Regarding the macrotheory, the general argument can be specified at several levels. The first is that a series of technological and organizational changes, especially since World War II, greatly increased the range of alternatives open to individuals and families about where they can live. Of particular importance has been the spread of highways into the areas surrounding central cities and almost universal ownership of at least one automobile by most American families. Also important are the substantially higher real incomes and the evolution of financial instruments (especially Federal Housing and Veterans Administrations' loan guarantees) which placed ownership of a single family dwelling unit within the reach of virtually the entire middle and much of the working class during the fifties and sixties.

Under these conditions, another set of variables presumably emerged as important. These were aspects of central city life, such as their high crime rates, regarded as unpleasant by whites and which could now be avoided, and the view that whites move to the suburbs for these reasons is a second level of explanation. Moreover, this explanation has emerged as the dominant one in popular treatments of suburbanization in the mass media and even in some more scholarly works.

A third set of variables is the relatively enduring structural characteristics of metropolitan areas. These influence the context within which individuals and builders make decisions about where they will live and where new housing will be located. The roots of these characteristics are in the growth history of the individual metropolis and include the size of the central city, the density at which it is settled, its ability to annex surrounding territory in the course of its development, and the distribution of jobs and housing between central city and suburbs.

Sociologists and economists have tended to focus their research on these structural variables and have paid little attention to such factors as crime and civil disorder. For example, Schnore (1965) suggested that the sheer inability of cities to contain the massive volume of new housing construction in the post-World War II years meant that it had to locate outside of their boundaries, resulting in large-scale suburbanization. One implication is that had cities been able to annex this surrounding territory, the "suburbanization" trend would have been much less pronounced. Others, such as Hoover and Vernon (1962), have emphasized the decentralization of jobs as a major factor attracting people to the suburbs, in addition to the location of new housing there.

It is toward a synthesis of the second and third of these frameworks that this research is directed. The first emphasizes changed transportation systems and credit instruments, and assumes these to be more or less constant across metropolitan areas; that is, individuals and families presumably have equal access to automobiles and loans to buy housing in Indianapolis as they do in Dallas. This is clearly not the case with the second and third types of variables such as central city crime rates and densities, conditions which vary considerably across metropolitan areas at any given point in time.

For convenience, these two classes of variables are classified as "push" and "structural." It is recognized that such factors as crime rates and black population size could be conceptualized as "structural" properties of cities. However, they are less enduring characteristics than, for example, central city densities, in the sense that they are much more amenable to short-term alteration by public policy or other forces. More importantly, this distinction is consistent with the way in which the theoretical questions are formulated. In the following paragraphs bivariate hypotheses are developed, linking each independent variable with white suburbanization, setting the stage for specification of a model within which the role of both frameworks in the suburbanization process can be examined.

Structural Variables

Density (DENSITY60). A theoretically crucial structural variable is the density at which the central city is settled. Not only is density expected to be a major constraint on the location of new housing and jobs, it is also closely associated with its age and reflects the dominant transportation mode in use when the city emerged. Since the type of transportation system fundamentally affected the extent to which jobs and population were initially suburbanized (Wood, 1958; Warner, 1962) and is a persisting characteristic of cities (Duncan et al., 1962; Guest, 1973), it is likely to be closely associated with job and housing suburbanization in 1960. Briefly, cities which emerged before 1890 were extremely compact since virtually everyone had to live within walking distance of their jobs and shopping districts. While the horse-drawn railway, widely adopted during the 1850s, altered the radius of urban settlement somewhat, very high densities prevailed. As late as 1879, for example, the average commute trip in New York City was only one-quarter of a mile (Pred, 1966:209-10).

Introduction of the electric railroad, as Warner (1962) showed in his study of the Boston area, led to rapid decentralization which heavily involved middle-class persons and marked the beginning of status differences between cities and suburbs (cf. Wood, 1958). As Tobin (1976:99) points out: "Urban space was redefined by the introduction and use of electric power by street railways." Automobile use expanded steadily after 1908, the year in which mass production of the Model T was begun. However, it was not until the 1920s that the automobile supplemented the electric railroad and became the dominant constraint in the distribution of population within metropolitan areas (Tobin, 1976:99).

Finally, density is closely related to the type and quality of a city's housing stock. In particular, it is likely to affect the percent of dwelling units built before 1950 (LT50), percent owner-occupied (OWNER60), and percent single family (PCTSINGLE60). While each of these characteristics tap somewhat different

dimensions of the quality of the central city's housing stock, all are expected to influence white decisions about a central city versus a suburban residential site. Population densities of central cities, housing type and quality, and the degree to which population and jobs are suburbanized are consequently intimately bound with one another, and a major question is the extent to which those factors affected further suburbanization in the sixties. (Sources of data and the operational definitions of all variables except RIOTS are given in Table 1.)

Annexation (ANNEX60 and ΔANNEX). Central cities vary considerably in their

ability to extend their political boundaries to contain the expanding urban development on their peripheries, and this may affect their ability to attract and hold whites in two ways: (1) to the extent that the central city contained a substantial portion of the metropolitan area's housing stock in 1960, a larger proportion of in-migrants was likely to settle there; and fewer residents were likely to leave, since they had a wider range of choice within the central city; (2) if the central city were able to annex surrounding territory between 1960 and 1970, similar effects on suburbanization are anticipated.

The first variable (ANNEX60) is de-

Table 1. Operational Definitions of Independent Variables and Sources of Data

1. *DENSITY60*. Population per square mile of the central city in 1960 (U.S. Bureau of the Census, 1962, Table 6).
2. *LT50*. Proportion of all central city dwelling units in 1960 which were built before 1950 (U.S. Bureau of the Census, 1962, Table 6).
3. *PCTSINGLE60*. Proportion of all dwelling units in the central city in 1960 which were single-family dwelling units (U.S. Bureau of the Census, 1962, Table 6).
4. *OWNER60*. Proportion of all central city dwelling units in 1960 which were owner occupied (U.S. Bureau of the Census, 1962, Table 6).
5. *ANNEX60*. Proportion of all dwelling units in the SMSA which were located in the central city in 1960 (U.S. Bureau of the Census, 1962, Tables 3 and 6).
6. *ΔANNEX*. Percent population increase between 1960 and 1970 due to annexation (U.S. Bureau of the Census, 1971, Table B; 1963, Table 20).
7. *NEWDUSUB*. Proportion of all dwelling units in the SMSA built after 1960 which were located in the suburbs (U.S. Bureau of the Census, 1972, Tables 3 and 6).
8. *JOBSUB60*. Proportion of all manufacturing, retail, wholesale, and service jobs in the SMSA in 1960 which were located in the suburbs (outside of the central city, but inside of the SMSA). The number of jobs in 1960 was estimated with a linear interpolation between the 1957 and 1963 census of manufacturing (U.S. Bureau of the Census, 1962, Tables 3 and 6; 1973, Tables 3 and 6).
9. *NEWJOBSUB*. Proportion of all new jobs and services in the SMSA between 1960 and 1967 which were located in the suburbs. The 1960 jobs are the estimates described in fn. 1 above, while the 1967 jobs were taken from Tables 3 and 6 of the 1972 City and County Data Book (U.S. Bureau of the Census, 1972). Of course, this is actually the estimated net gain for the SMSA between 1960 and 1967 since many jobs and services left during the period.
10. *SIZE60*. 1960 total population of the central city (U.S. Bureau of the Census, 1963, Table 20).
11. *REGION*. A dummy variable scored 1 if the SMSA was located in the Southern Census region, 0 if not. The states located in the Southern Census region are: Alabama, Arkansas, Delaware, Florida, Georgia, Kentucky, Louisiana, Maryland, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, Virginia, West Virginia.
12. *PCTBLACK60*. Percent of the total central city population in 1960 which was nonwhite (U.S. Bureau of the Census, 1962, Table 6).
13. *TAXES60*. Ratio of the total dollar property taxes paid by central city residents in 1960 to the total 1960 central city population (U.S. Bureau of the Census, 1962, Table 6).
14. *CRIME60*. The estimated number of 1960 murders, non-negligent manslaughter, forcible rapes, aggravated assaults, and burglaries, divided by the total central city population in 1960, multiplied by 100,000. The estimate was obtained by averaging the numbers of each type of crime for 1959, 1960, and 1961 (U.S. Federal Bureau of Investigation, 1960, 1961 and 1962).
15. *RIOTS*. Index of riot frequency. Operational definition and sources of data described in text.
16. *ED60*. Per capita expenditures on public school children in the central city in 1950 (U.S. Bureau of the Census, 1962, Table 6; U.S. Bureau of the Census, 1963, Table 73).
17. *CCTOSUB*. Estimated proportion of central city residents in 1967 who moved to the suburbs of that city (U.S. Bureau of the Census, 1973a).
18. *INTOSUB*. Proportion of in-migrants to the SMSA between 1965 and 1970 who moved to the suburbs (U.S. Bureau of the Census, 1973a).

defined as the proportion of all of the metropolitan area's dwelling units contained in the central city in 1960. (This definition is used in preference to the more customary proportion of the total metropolitan population within the central city [e.g., Schnore, 1965:210] because it more directly indicates the ability of the city to contain the built-up area.) The second variable (ΔANNEX) is percent increase or decrease between 1960 and 1970 in the central city population due to annexation. (This index of change is used instead of changes in the number of dwelling units in annexed territory because the necessary data are not readily available.)

Job suburbanization (JOBSUB60 and NEWDUSUB): The third structural variable is the distribution of manufacturing, retail, and wholesale jobs between central cities and suburbs in 1960. This distribution has been shown in other contexts to be an important location constraint on households, largely because households generally attempt to minimize the length of the journey to work, *ceteris paribus* (Carroll, 1949; 1952; Hoover and Vernon, 1962; Kain and Nidercorn, 1975; McAllister et al., 1971; Schnore, 1954). Service and retail activities are also likely to attract population since they represent important amenities, and these are combined with manufacturing and retail jobs to simplify the analysis. The hypothesis is that whites were attracted to the suburbs of metropolitan areas where jobs and services were decentralized in 1960.

A closely related variable is the distribution of jobs added to the metropolitan area between 1960 and 1967 (NEWJOB-SUB). The distribution of new jobs is distinguished from that of jobs in 1960 because both are expected to have independent effects on the distribution of new dwelling units and white suburbanization.

Suburbanization of new dwelling units (NEWDUSUB): A powerful determinant of the location of households is likely to be the location of new housing. This is probably for in-migrants to metropolitan areas as well as for central city residents. While many of the former will be attracted to older housing, it is anticipated that most will flow into newer units, whether located in the central city or its suburbs. At

the same time, newly formed households in central cities, or families which enter the child-bearing stage of the family cycle, are likely to prefer new housing because it tends to be more spacious than older units (McAllister et al., 1971; Rossi, 1955), regardless of its location.

Regional location and size (REGION AND SIZE60): Finally, the possible effects of regional location of the SMSA and the 1960 size (SIZE60) of the central city are considered. Both, especially region, reflect a complex of factors, including historical differences among metropolitan areas in the numbers of blacks, the distribution of blacks and high-status persons between central cities and rings, the period in which they experienced their initial suburban expansion, and their age. For these reasons, although there is little substantive interest in these variables per se, it is necessary to control them to avoid misspecifying the structural equation model developed here.

Push Variables

Civil disorder. Turning now to push variables (negative characteristics of central cities which lead whites to leave and/or to avoid them in the first place), a frequently mentioned variable is civil disorder. While many studies have addressed the causes of civil disorder, especially riots (e.g., Jiobu, 1971; 1974; McElroy and Singell, 1973; Spilerman, 1970; 1971) and their severity (Wanderer, 1969; Spilerman, 1976), none has examined their consequences. However, this is frequently cited as an important component in the explanation of white suburbanization. Civil disorder has a number of dimensions: strikes by municipal employees such as teachers and policemen, civil rights protests, and race riots. Furthermore, each of these has subdimensions, such as duration in days, numbers of persons involved, and, in many, numbers of persons injured and/or killed, dollar loss, and numbers of persons arrested.

Measures of each dimension of civil disorder were obtained for each central city, and a series of factor analyses performed to create indices of the various dimensions. The general hypothesis is that

each is positively related to white suburbanization. However, interesting empirical questions are: which dimension has the strongest relation and what is the degree to which any correlation reflects a causal impact?

Crime rate (CRIME60). Another frequently listed negative feature of central city life which presumably affects suburbanization is a high crime rate (e.g., Gold, 1970; Wilson, 1970). Berry (1975:178) neatly summed up this view with his remark that "violence . . . is a pervasive underpinning of central city life." President Johnson's Task Force on Individual Acts of Violence (1970) suggested that crime is contributing to the emergence of the "defensive city," where suburbs, physically distant from the central city, will be "safe areas." However, almost no attempt has been made to actually evaluate the impact of this variable on white suburbanization. The measure of CRIME60 is the rate per 100,000 persons of the number of reported murders, non-negligent manslaughters, forcible rapes, aggravated assaults, and burglaries (breaking and entering). These crimes were chosen because they most directly represent threats to personal safety.

Taxes (TAXES60). The very high property taxes which central city residents pay are often cited as an important reason for the loss of jobs and white population. This variable is defined as the ratio of the total property taxes paid by the residents of the city in 1960 to the total population in that year. It is expected that TAXES60 has positive effects on both measures of white suburbanization.

Percent black 1960 (PCTBLACK60). One of the most emotionally charged issues of the seventies is the role of black population size in white suburbanization. In usual versions of explanations, considerable emphasis is given to white racism—the feeling that whites simply will not live in cities where the black population is large. Whites presumably desire to minimize contact with them—contact which is necessarily high under such circumstances, especially in public places (cf. Berry, 1973:53; Rose, 1976:7). Therefore, a positive relation is antici-

pated between PCTBLACK60 and the two measures of white suburbanization.

School quality (ED60). The quality of local schools is often assumed to be an important consideration by whites in the calculus about where they will live. In particular, the higher quality of suburban compared with central city schools has been emphasized as a major factor contributing to the "flight" of whites to the suburbs during the sixties. While this consideration is especially salient for families with children, many presently childless couples may anticipate having children at some future time and therefore base their location decisions in part on school quality.

This variable is not easily quantified, particularly for units as large as cities where there is considerable intradistrict variation in the quality of schools. The operational definition used here is per capita expenditures on public school children. The amount of money spent per child affects the salaries of teachers and the extensiveness of facilities, such as laboratories and libraries, as well as special services. The specific hypothesis is that per capita expenditures in central cities is inversely related to the two measures of white movement to the suburbs.

Another component of school quality is the frequency with which the system was disrupted by strikes and racial disorders, as well as their severity. The sixties was a period in which teacher unions became increasingly militant, especially during the later years when the whites studied here were making their decisions. There were also numerous school closings because of racial confrontations. As described in the methods section, a number of dimensions of school disorder were operationally defined and emerged as distinct factors in the factor analysis. It is anticipated that the index created from this factor is positively related to white suburbanization.

METHODS

Units of Analysis and Operational Definitions

*The units of analysis are metropolitan areas which had a central city of 100,000

or more in 1960, where the central city and the SMSA in 1970 were not coterminous. This subset was selected from all SMSAs because there are major structural differences between large and small metropolitan areas especially in the tendency for high status persons to be relatively concentrated in the central cities of the latter (e.g., Schnore, 1965). The two SMSAs from which counties were deleted to form new SMSAs (San Francisco-Oakland and Los Angeles-Long Beach), as well as the three SMSAs where the number of central cities in 1970 differed from 1960 (Winston-Salem, Seattle-Everett, Beaumont-Port Arthur-Orange) were also deleted. The final N is 112.

There are two dependent variables, both of which are taken from the Fourth Count Summary Tapes of the 1970 Census of Population and Housing (U. S. Bureau of the Census, 1973a). The first dependent variable is an approximation of the probability that central city residents in 1965 moved to the suburbs of that central city between 1965 and 1970. This variable is defined as:¹

$$\frac{\text{Probability of white central city residents moving to suburbs (CCTOSUB)}}{\text{White residents five years of age or older of the central city in 1965 who resided in the suburbs in 1970}} = \text{mid-1967 central city white population}$$

No distinction is made in this analysis between the two stages of mobility from central cities to suburbs—the factors affecting the decision to move compared with those affecting the choice of a specific location (city versus suburb, in this case). This is not done because primary interest is in direct comparison of the pattern of causes for the two measures of population suburbanization. (For an excellent discussion of this distinction see Frey 1978.)

The second dependent variable is an approximation of the probability that in-migrants to the metropolitan area between 1965 and 1970 settled in the suburbs. This variable is defined as:²

$$\frac{\text{Probability of a white in-migrant to the SMSA settling in the suburbs (INTOSUB)}}{\text{White suburban residents five years of age or older in 1970 who lived outside of the SMSA in 1965}} = \text{White SMSA urban residents in 1970 who lived outside of the SMSA in 1965}$$

¹ This is only an approximation of the "true" probability for three reasons: (1) it underestimates the true probability because it does not include persons who moved to the suburbs between 1965 and 1970 and then either moved back to the central city or outside of the metropolitan area; (2) the mid-1967 white population of the central city is an estimate obtained on the assumption that it grew (or declined) at a constant rate each year between 1960 and 1970; (3) it does not take into account mortality among those who moved to the suburbs and then did not survive until 1970.

Note that the denominator refers to the mid-1967 estimate of the central city population because persons reported as living in the suburbs in 1970 and the central city in 1965 moved in 1965, 1966, 1967, 1968 or 1969. Assuming that movement was evenly distributed over each of these years, then the appropriate base population is the midpoint of the interval—mid-1967, the year in which the average migrant to the suburbs moved there. While some ambiguity remains by use of the mid-1967 base since it includes persons born between 1965 and that point, it has a clearer theoretical meaning. Moreover, since the numbers of persons involved are quite small in comparison with the remaining population, the resulting zero-order and partial correlation coefficients are virtually identical to those obtained when the 1965 base is used.

² As with CCTOSUB, this understates the true probability since it does not include persons who first moved to the suburbs and then to the central city, or those who moved in and then out of the SMSA between 1965 and 1970. It also does not include persons who moved to the suburbs and did not survive until 1970. Unlike the denominator for CCTOSUB, the denominator for INTOSUB refers to in-migrants only. While it is true that these persons could have moved into the SMSA at any time between 1965 and 1970, concern is with how the entire group of in-migrants was distributed, and the idea of a mid-year is not relevant.

The "suburban" population is defined as the urban white population outside of the central city but within the boundaries of the SMSA. That is, a "suburbanite" is a person who lives in a place of 2,500 or more, or in a densely settled area coterminous with a city of 50,000 or greater, but not in the central city. The urban population in the ring is used in preference to the entire ring population because in many metropolitan areas this latter group contains a substantial rural component. In fact, in 1970 more than 25% of the total population within SMSAs but outside of their central cities was rural (Farley, 1976:5). However one defines "suburban," such persons are not likely to be included. In metropolitan areas with more than one central city, these were combined.

The indices of civil disorder were developed from several sources. As part of a broader study of civil disorder and violence in United States cities during the sixties, data on several general categories of this concept were obtained for each central city and each year from 1965 through 1969. These categories, and their operational definitions, were:

(a) *Civil rights protests*. Organized protests by blacks, involving at least 30 persons.

(b) *Violent incidents*. Unorganized spontaneous outbursts of black violence involving small numbers (30-100) of blacks and of relatively short duration (usually three days or less) and with relatively small amounts of property damage (less than \$100,000).

(c) *Riots*. Unorganized, violent outbursts of blacks involving large numbers (100 or more) of blacks, of relatively long duration (more than three days), with relatively substantial property damage (\$100,000 or more), and loss of life or significant numbers of personal injuries.

(d) *Municipal services*. Strikes by personnel providing important city services, such as mass transit operators, garbage collectors, and hospital, police, and fire personnel.

(e) *School closings because of interracial fights between students*. At least one day's duration.

(f) *Teacher strikes*. An organized group

of teachers (e.g., union) not teaching for at least one day.

For each of these general categories several specific items were obtained. In the case of riots, the following information was coded for each: duration in days; number of persons killed; number of persons injured; estimated property damage in thousands of dollars; number of persons involved; and number of persons arrested. For all other categories appropriate data on the intensity and extensiveness of each was coded.

The principal source of data was the *New York Times Index*. For each year the various relevant headings were searched, and if an incident from one of the above categories occurred in a central city of an SMSA, the data was coded.³ The data for riots and racial incidents was supplemented by the reports of the Lemberg Center for the Study of Violence (1968a, b) and the Report of the National Advisory Commission on Civil Disorders

³ Since virtually all of the data on the various types of civil disorder came directly or indirectly from the *New York Times Index*, there is some question about the completeness of its reporting. Even the riot data, which was supplemented by the additional sources cited above, are based primarily on newspaper reports, especially the *New York Times*, the *Washington Post*, and the *Washington Star* (Danzger, 1975). The potential problem, of course, is that many incidents will not find their way into these publications, either because they are never reported to them or because they are not considered important enough to interest New York or Washington readers.

The only systematic analysis of this question is Danzger's (1975) study of the validity of his own data on black-white conflicts in cities. He found that the presence of an AP/UPI office was strongly related to whether a conflict event was reported in the *New York Times*. Since the units used in the present study are very large metropolitan areas, most have an AP or UPI office in at least one city in the SMSA. Consequently, this source of contamination is largely controlled. Furthermore, Danzger (1975) argues that reports of the details of a conflict event, such as numbers of participants, are valid because of the self-correcting nature of news reporting. While the riot data are consequently assumed to be valid, this may not be the case with the other disorder data. A teacher or hospital strike in Dallas, for example, may be less likely to be reported in the *New York Times* than a riot in that city because it is less likely to be defined as "important" for New York readers. Because of this, the validity of the indices of these other variables is less clear than in the case of riots and riot characteristics, and this should be considered in interpreting the findings.

(1968). Each incident was cross-checked to broaden the information contained in the *New York Times Index*. Finally, the data for each variable (duration in days, estimated property damage, etc.) were aggregated for the 1965–1969 period. For each central city, this aggregation produced separate variables referring to the total number of days in which rioting occurred between 1965 and 1970 and total estimated property damage during that period.⁴

Measurement Issues

Finally, two methodological issues, with theoretical implications, are considered. The first is whether the independent variables should refer to the position of the central city relative to its suburbs, or to the central city only. It is clear that an individual's decision about where he or she will live is based upon comparison of the net advantages of one site compared with another. For example, if crime and/or the presence of blacks are salient considerations in this calculus, it is evident that there will be net flow away from sites where crime rates and the number of blacks are high toward those where both are low. This suggests that the appropriate type of variable is the relative position of suburbs and cities—for example, the ratio of the percent of blacks in the suburban population to the comparable percent in the central city, or the ratio of the suburban to the central city crime rates.

However, this reasoning is based on the assumption that the "suburbs" comprise a single community. More precisely, it assumes that crime rates and the relative size of black populations are the same in each suburb. In fact, this is not the case. As Hermalin and Farley (1973) showed for blacks, and Stahura et al. (1980) for crime rates, there is tremendous variation across suburbs on both. It is likely that this is

also true for many of the other variables used in this study, and consequently inferences based on the correlations of relative position variables involve a kind of ecological fallacy. Consequently, the most valid type of independent variable refers to characteristics of the central cities only. The exceptions, for reasons developed here, are the distribution of jobs and dwelling units.

In other words, it is assumed that if crime is an important consideration for whites about where they will live, and if the crime rate is high in the central city, then they will be able to find a suburb where the crime rate is low. To the extent that suburbs of particular metropolitan areas are *not* heterogeneous with respect to one another and to their central city, then the observed correlations between white movement to the suburbs and such variables as crime and tax rates, for example, are biased. However, since the analysis is restricted to large metropolitan areas, the assumption of heterogeneity seems warranted. (For further discussion of this question see Bradford and Kelejian, 1973.) This reasoning is applied to all of the push variables previously described.

This reasoning does not apply to the distribution of jobs and dwelling units—in the case of jobs, because of the considerable variation in the degree to which suburbs are net importers or exporters of labor (Schnore, 1965:175–7). The result is considerable intrasuburban movement of workers—the fastest growing commute in metropolitan areas (Meyer, 1970). In other words, to the extent that jobs are relatively concentrated in the suburban ring, compared with the central city, workers are expected to move to the former, even though they may not settle in the same suburb where they work. This differs from the rationale for a variable such as crime, where the individual is comparing the levels in the central city with those in a particular suburb, and consequently where the aggregate crime level in all suburbs is not relevant.

In the case of the location of new dwelling units, it is expected that population flows into new housing wherever it is located. If the bulk of these units is placed in the suburbs, then the bulk of

⁴ The headings most commonly used were: Education, U.S., Racial Integration, Negroes, Housing Discrimination, Riots, Teachers, Government Employees, etc. The headings changed somewhat from year to year. When the summary in the index was incomplete, the newspaper article on which it was based was examined, using microfilmed copies of the *New York Times*.

in-migrants or central city families who require it will relocate there. The issue of suburban heterogeneity is not relevant. If, for example, a substantial quantity of new housing is placed in an older suburb, families which can afford it will move there.

The second issue is the point in time to which the variables refer. Of course, this is not problematic for region, size, JOB-SUB60, ANNEX60, DENSITY60, the indices of new jobs and housing, or either measure of suburbanization. The time to which taxes, percent black, and crime should refer is more problematic. From one point of view, each should refer either to 1965 or the midpoint of the 1965-1970 interval. However, correlations of variables measured at this point in time with the suburbanization measures will be upwardly biased (Greenwood, 1975).⁵

There are also theoretical reasons to prefer 1960 levels of variables. It seems likely that these have a lagged effect on white suburbanization. Perceptions about the size of a city's black population or its tax levels, for example, are probably diffused slowly and there is likely to be a gap between dissemination of such information and present levels. Whether the lag chosen here is the appropriate one is an empirical question which cannot be directly answered with the available data. These issues do not arise for riots and the measures of the distribution of new jobs and dwelling units since they are not estimates, nor is the question of a lag relevant.

⁵ Data are not available for years between the decennial censuses of population, with the exception of crime data. Consequently, estimates must be obtained using some kind of interpolation, usually linear, between 1960 and 1970. The source of the bias is most evident for percent black if estimated using this technique. If large numbers of white in-migrants to the Chicago SMSA, for example, chose the suburbs, then the percent of the Chicago central city which was black will be higher than if small numbers made this choice. If a linear interpolation of the 1960 and 1970 numbers of central whites and blacks is then used as part of the denominator, this estimate will be influenced by the relative size of the suburban stream going to the suburbs. Consequently, a correlation will be "built in" between white suburbanization and the estimate of percent black in 1967, resulting in an upward bias. A similar argument is made for taxes and LT50.

FINDINGS

Factor Analyses

The first concern is construction of indices of civil disorder and their relation to white suburbanization. The specific version of factor analysis used was the principal components technique. Several factor analyses were performed, using somewhat different subsets of measures from each of the classes of variables described above. It was necessary to limit the number of variables in each analysis since the number of cities was only 112.

Several factors emerged that tended to be fairly stable for each analysis: teacher strikes, public employee strikes (other than teachers), riot severity, riot frequency, and civil rights protests. On the basis of the factor coefficients, indices of each factor were constructed and correlated with the two measures of white suburbanization. However, only the two riot factors were even moderately correlated with these dependent variables. Indeed, individual measures used to construct the indices sometimes had higher correlations than the indices themselves. Of course, it does not follow that these are unimportant dimensions of civil disorder, nor that they are unrelated to any aspect of white suburbanization. (This question is pursued in a separate study.)

In the context of the present study, the findings that most aspects of civil disorder are unrelated to white suburbanization are important negative results. It appears that, contrary to popular notions about the etiology of the suburban trend, civil unrest in large cities during the sixties was largely unrelated to the decisions of white central city residents to move to the suburbs or of in-migrants to locate there. In particular, municipal employee strikes (other than teachers), teacher strikes and school closings due to interracial violence, and civil rights protests apparently played little or no role in these decisions.

However, such may not be the case with race riots, and this variable was further analyzed. To obtain more stable indices the full range of specific characteristics of riots were separately factor analyzed, again using the principal components technique. Two clear factors

emerged from the analysis. The first suggests a "seriousness" dimension, and the second a "frequency" dimension. When indices were constructed representing each of these dimensions, using the factor coefficients, the frequency factor was much more strongly correlated with both measures of white suburbanization than the seriousness factor. Whites are apparently much less concerned with the amount of damage caused by riots than they are with their frequency and duration—a substantively interesting finding.

Correlation Analyses

Next, the zero-order relations between the independent variables explicated here, including riot frequency (RIOTS) and the two measures of white suburbanization, are examined and presented in Table 2 along with the means and standard deviations. The indices of riot seriousness as well as the other indices which emerged from the first factor analysis are not examined further because of their small correlations with the two measures of suburbanization.

Before examining these relations in detail, it was necessary to test the hypothesis that they are linear. This was done by determining whether an equation containing a curvilinear term significantly incremented the variance explained by a linear equation (Namboodiri, et al.,

1975:153). Statistically significant departures were observed for a number of relations. However, statistical significance does not necessarily mean that there is a substantively important nonlinear trend. The latter can be inferred from a graph in which coefficients from the significant curvilinear equations are used to plot the actual curves. This operation indicated that all of the statistically significant curvilinear trends are, for all practical purposes, linear. Consequently, the assumption that the relations between the independent variables is linear does not seriously distort the data, and subsequent discussion and analysis is based on it.

The correlations in Table 2 provide an indication of the strength of the various associations, if not their causal impact. Many are substantial and most are consistent with the hypotheses outlined above. However, there are some surprising exceptions, particularly in the case of PCTBLACK60 and ED60. PCTBLACK60, although in the predicted direction, is small compared with many of the other variables. In the case of ED60, the correlation with CCTOSUB is virtually zero, and the correlation with INTOSUB is small. The strongest relations with white suburbanization are with ANNEX60 and NEWDUSUB, although DENSITY60, JOBSUB60, PCTSINGLE60, LT50 and RIOTS also have moderate to strong relations with it.

The only clear pattern in Table 2 is the

Table 2. Correlations Between Independent Variables and Population Suburbanization

	CCTOSUB	INTOSUB	\bar{X}	S
DENSITY60	.31	.40	5,982	4,133

SIZE60	.06	.09	413,372	818,412
REGION	-.18	-.28	.35	.48
CCTOSUB72	.08	.06
INTOSUB	.7248	.22

general tendency for the correlations between the independent variables to be larger with INTOSUB than with CCTOSUB, and many of the differences are substantial. One possible interpretation of the pattern is inertia. By definition, in-migrants to metropolitan areas are in the process of changing residences, and they may be much more affected by negative features of the central city and/or its position relative to the suburbs. Central city residents, on the other hand, must be induced to move, and it may take a much greater degree of "push" and/or "pull" to set them into motion.

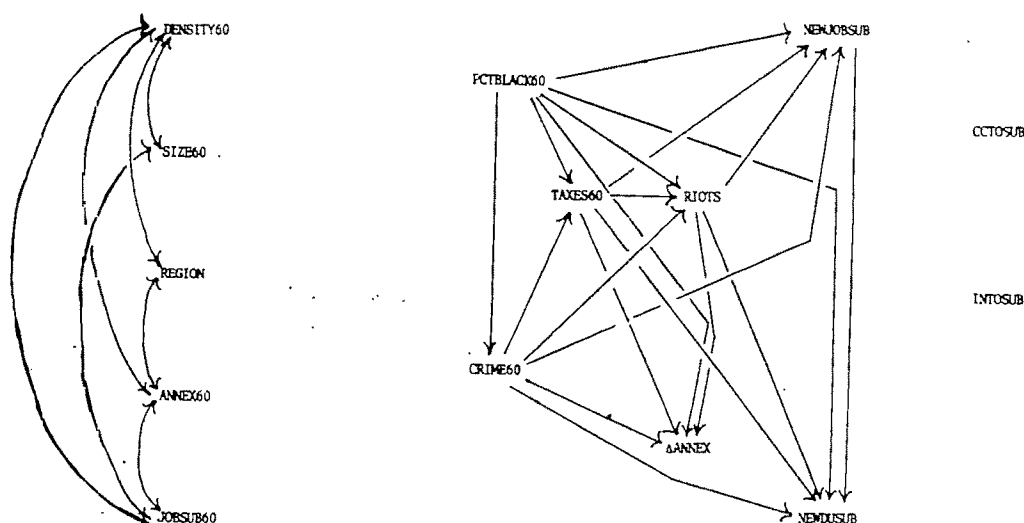

Multivariate analysis

Finally, path analysis is used to explore the question of the degree to which the correlations reported in Table 2 represent causal impact. Concern is with that part of the total association between the independent variables and suburbanization which is spurious, as well as the process through which the former affect suburbanization. Path analysis requires specification of the causal order among the variables, as well as the assumption that variables not included in the model which affect particu-

lar endogenous variables do not affect others (e.g., Duncan, 1975).

Several alternate specifications are possible, given the large number of variables involved in the study, many of which tap alternate dimensions of the same underlying concept, and the mix of cross-sectional and dynamic variables. The particular specification evaluated here is summarized in Figure 1. Following the usual convention, each hypothesis is represented by an arrow linking two variables. However, arrows linking the exogenous with the endogenous variables are not shown, nor are those linking the independent variables with the two measures of population suburbanization. The large number of additional arrows would make the diagram needlessly complex and consequently difficult to follow.

It should be understood that, unless otherwise specified, the hypothesis that each exogenous variable affects all endogenous variables is implied and analyzed, and that all independent variables are hypothesized to affect both measures of suburbanization. In cases where no causal link is assumed, the implied hypothesis is that the partial correlation between these variables, with other

^a Arrows linking the exogenous variables with the endogenous variables are not shown, nor are the arrows linking the independent variables with the two aspects of white suburbanization. The arrows are omitted because their inclusion would enormously complicate the diagram, and the implied causal order is clear.

Figure 1. Path Diagram ^a

exogenous variables controlled, is zero. The entire model is thus overidentified and recursive.

The principal criterion for inclusion of variables in the model is their theoretical importance, although the size of the zero-order correlations with the two measures of suburbanization was also considered. The latter criterion led to the exclusion of the various measures of civil disorder, except riot frequency and duration (RIOTS) and educational quality (ED60). In fact, when these variables were included in a model which also contained the variables displayed in Figure 1, none had significant direct or indirect effects on suburbanization.

The rationale for the general distinction between exogenous and endogenous variables largely follows from the earlier distinction between structural and push variables. Most of the former are assumed to be exogenous, not causally dependent on one another, although they are expected to be correlated. (These hypotheses are reflected by the curved arrows linking those variables in Figure 1.) They are not ordered with respect to one another because, as indicated in the theory section, they are relatively enduring structural characteristics of metropolitan areas which evolved over many decades, and it is not likely that they influence one another over short periods of time.

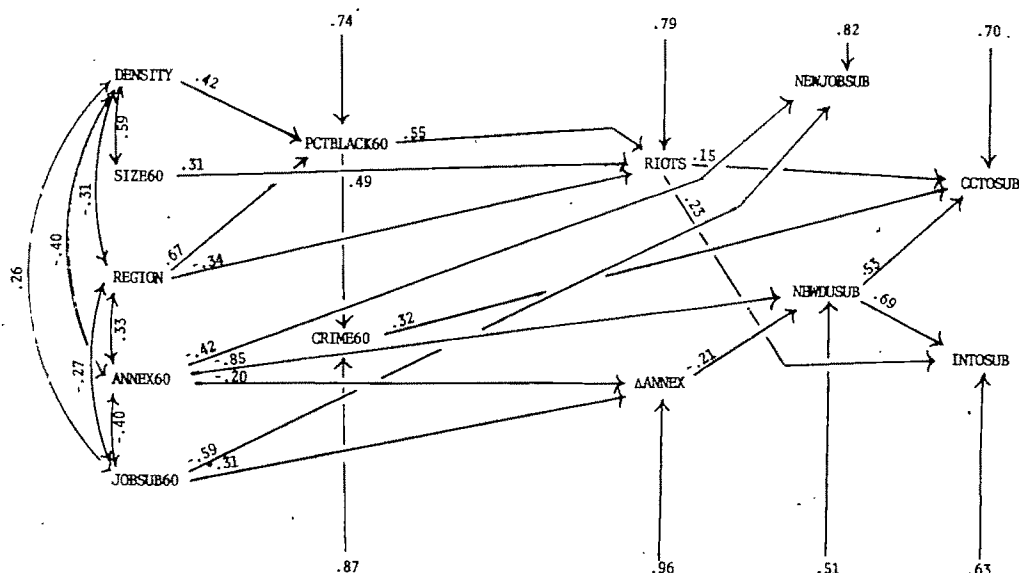

The endogenous variables, on the other hand, are regarded as more subject to short-term change and are considered causally dependent on the exogenous variables, with exception of JOBSUB60 and ANNEX60, for reasons given here. The general argument is either that the levels of endogenous variables are almost simultaneously determined by the level of other endogenous or exogenous variables, or that the exogenous variables, because of their greater stability, clearly emerged before the endogenous variables. For example, the crime rate in 1960 is assumed to more-or-less immediately affect the tax rate, as is the size of the black population, largely because the latter variable is a proxy for low-income persons. Regarding the relation between the endogenous and exogenous variables, the only ambiguous relation is with percent black.

It is assumed here that the relative levels of the exogenous variables were largely established prior to black population growth.

Considering specific relations, RIOTS are assumed in this specification to be a function of all prior variables except JOBSUB60 and ANNEX60. Because of the points in time at which RIOTS and the variables assumed to precede it are measured, it is obvious that the latter set cannot be affected by RIOTS, and the direction is clear. What is less clear are the possible effects of variables other than PCTBLACK60 and region. DENSITY60 and size may reflect the overall degree of social control or stability, while high taxes may produce resentment on the part of blacks. High crime rates may also reflect an underlying instability which makes riots more likely. In the case of PCTBLACK60 and region there is clear evidence that the size of the black population and southern location affected the frequency of riots during the sixties (e.g., Spilerman, 1971).

RIOTS may also have some inhibiting effect on the ability of the central city to attract new jobs and housing as well as to annex surrounding territory. Business and housing contractors may tend to avoid central cities where there were frequent riots, and these cities may also have some difficulty annexing surrounding territory. Similar arguments are made for PCTBLACK60 and CRIME60. Finally, PCTBLACK60 is hypothesized to affect CRIME60 indicated above.

Turning to the remaining relations between the exogenous and endogenous variables, note that none of the direct measures of central city housing quality are included in the model. Instead, because of its more clear-cut theoretical meaning, only DENSITY60 is represented. As suggested earlier, central city density is closely associated with the transportation era within which it emerged, and, consequently, with its age and the amount of older, multifamily housing. The latter is expected to affect crime and tax rates through its impact on the size of the poverty population. It is also expected to affect the size of the black population, since blacks have historically been at-

* Path coefficients not significant at the .05 level have been deleted and the model refitted. TAXES60 is also omitted because it had nonsignificant effects on CRIME60, JOBSUB60, RIOTS, NEWJOBSUB, or NEWDUSUB, or on either measure of white population suburbanization. While NEWJOBSUB had no significant effects on NEWDUSUB or on either measure of white population suburbanization, it is retained in the figure for reasons given in the text.

Figure 2. Path Diagram with Path Coefficients*

tracted to such housing, as well as the ability of the city to annex surrounding territory. Finally, density may affect taxes, largely through its effect on the crime rate and black population size. In short, DENSITY60 is the best single summary index of a number of closely related characteristics. However, alternate specifications using LT50 or PCT SINGLE lead to essentially the same conclusions.

The likely effects of ANNEX60 are clear.⁶ Central cities which contained a large proportion of the SMSAs 1960 housing are expected to attract relatively more jobs and new dwelling units, and also to

annex population between 1960 and 1970. However, there is no reason to anticipate any effect of this variable on RIOTS, TAXES60, CRIME60, or PCTBLACK60, as indicated before. JOBSUB60 is expected to affect the volume of suburban housing construction, on the assumption that new housing is located proximate to jobs. There may also be an effect on the location of new jobs, as well as on the ability of the city to annex surrounding population. There are no reasons to expect JOBSUB60 to affect any of the other endogenous variables.

The relations between size and region and the endogenous variables are not specified in detail. Both are proxies for a number of unmeasured variables, and it is pointless to specify hypotheses linking each to the host of variables which follow them. They are included primarily as controls, and there is little theoretical interest in their effects per se.

The specification, summarized in Figure 1, permits examination of the key questions to which the research is addressed, and the results of the path analysis are presented in Figure 2 and Table 3. The

⁶ Many of the SMSAs added counties during the sixties, and two lost a county. The former were deleted from the study. However, it is possible that the addition of counties affected the two suburbanization measures as well as the distribution of new jobs and dwelling units. To examine this possibility the ratio of the 1970 to 1960 SMSA land areas was correlated with these variables, and all were very small and not statistically significant at the .1 level. Moreover, when this boundary change index was included as a regressor in the equations for NEWJOBSUBS, NEWDUSUB, CCTOSUB, and INTOSUB, it remained small and nonsignificant.

¹ Columns 1, 3, 5, 7, 9, and 11 refer to CCTOSUB, while columns 2, 4, 6, 8, 10, and 12 refer to INTOSUB.

² The total association is the zero-order correlation between an independent and a dependent variable. In path analysis this association is decomposed into component parts: direct effects; indirect effects; a spurious component in the case of endogenous variables, a joint component in the case of exogenous variables.

³ The total causal (effect) is the sum of the direct and indirect effects in the case of endogenous variables. In the case of the exogenous variables the joint effects are included in the total. Although this is not customary, it is consistent with the text discussion of the effects. The sum of the joint and indirect components does not correspond to the zero-order correlation coefficient because statistically nonsignificant paths were deleted and consequently the correlation coefficient is not the sum of the joint, direct, and indirect effects. However, the observed correlations tend to be quite similar to the reproduced correlations. Furthermore, in the case of the endogenous variables, since the spurious component was obtained by subtracting the direct and indirect effects from the correlation coefficient, there is some ambiguity in its interpretation.

⁴ The direct effect is the path coefficient, the proportion of the standard deviation of each measure of suburbanization accounted for by the independent variable after the effects of all other variables in the equation have been controlled.

⁵ The indirect effect of a variable is its effect on the dependent variable through its effects on other variables in the model which in turn affect the dependent variable.

⁶ The joint component is that portion of the zero-order correlation between an exogenous variable and the two measures of white suburbanization due to its correlation with other exogenous variables which in turn cause variation in the dependent variable.

⁷ The spurious component is that portion of the zero-order correlation between an exogenous variable and the two measures of white suburbanization due to its correlation with other exogenous variables which in turn cause variation in the dependent variable.

model was fitted twice. The second, schematically represented in Figure 2, resulted from deleting from the first model paths which were not significant at the .05 level. While somewhat arbitrary in view of the fact that almost all of the variables are based on population data, the population suburbanization indices are based on a 15% sample, and a significance test is consequently required. Moreover, the magnitudes of almost all of the paths deleted using this significance level were between .00 and .10, and their elimination greatly simplifies the model's interpretation. Retention of such small paths would have greatly increased the model's apparent complexity without affecting the substantive interpretations.

The data in Figure 2 and Table 3 have

clear implications for the popular interpretation of white movement to the suburbs as "flight." Central city tax rates had no causal impact, direct or indirect, on either measure of white suburbanization and it is consequently not represented in Figure 2; its moderate zero-order correlation with white suburbanization is apparently entirely spurious (Table 3). While riots had some direct effect on both measures of white suburbanization, it is quite small compared with the distribution of new housing, suggesting that riot frequency played a very minor role.

The strongest direct support for the "flight" hypothesis is the moderate impact of CRIME60 on the probability that a central city white moved to the suburbs. However, this variable had no effect on

the probability that a white in-migrant settled in the suburbs, and this is the principal difference between the causal structures for INTOSUB and CCTOSUB.

The process through which the relative size of the black population affects white decisions to move to the suburbs is also inconsistent with the popular view that whites are fleeing blacks. Not only is its causal impact small compared with other variables in the model (Table 3, cols. 3 and 4), its impact is entirely indirect. Central city whites are apparently not concerned about the relative size of the black population *per se*; or, if they are, this concern is not reflected in decisions to move to the suburbs. Instead, it is only because large black populations are associated with high crime rates and frequent riots that whites leave central cities, and even this indirect effect is not large. In the case of white in-migrants, the indirect effect is much smaller.

The similarities between the two causal structures are more pronounced than their differences. The primary constraint on decisions by white in-migrants to metropolitan areas and central city residents about whether they will live in the suburbs is the location of new housing. This does not mean that they are not concerned with crime, at least in the case of central city residents, only that the concern is less important. All of the other independent variables operate entirely through CRIME60 and NEWDUSUB.

Indeed, looking at the entire model displayed in Figure 2 and Table 3, a rather clear and quite plausible picture of the process of white movement to the suburbs during the late sixties, or at least that portion represented by the two dependent variables analyzed here, emerges. A key factor was the extent to which the central city had historically been able to contain a substantial portion of the built-up area of the SMSA within its boundaries (ANNEX60). This was the dominant determinant of whether it was able to capture new housing development, which in turn was the major constraint on the movement of whites to the suburbs.

The lack of any direct effect of ANNEX60 on population suburbanization is somewhat surprising and suggests that

this variable primarily indexes the availability of space suitable for further residential development proximate to the city center. If such space was available, then new housing tended to flow into the central city; if it was not, then this housing was relatively concentrated in the suburbs. It does not appear that individuals and families were directly attracted to central cities in which the metropolitan area's housing stock was relatively concentrated.

The only other variable directly affecting NEWDUSUB was population annexation between 1960 and 1970—a relatively small effect. The absence of any effects of riot frequency and duration, crime, and percent black on NEWDUSUB is also interesting and strongly suggests that developers do not respond to these variables when deciding where to locate new housing.

However, it also appears that developers do not respond to the 1960 location of jobs and services, or the distribution of new jobs, when making location decisions. These patterns, coupled with the lack of any direct effects of the job distribution variables on either population or new dwelling unit suburbanization, are the major unanticipated findings of the study. The only impact of job distribution was JOBSUB60's very small and negative effect through Δ ANNEX. Most of the moderate relation between JOBSUB60 and population suburbanization reflects its correlation with ANNEX60. Metropolitan areas where the central city contained a large proportion of the jobs in 1960 also tended to contain a large proportion of the housing stock which largely accounts for the observed correlation. These data suggest that metropolitan areas are unified communities in which the labor force is sufficiently mobile to locate their residences without concern for their places of work.

NEWJOBSUB is included in Figure 2, even though it has no direct or indirect effect on population suburbanization. The pattern of coefficients suggests that racial considerations, along with central city crime and taxes, played no role in decisions about where to place new jobs. Instead, the most important consideration apparently was the extent to which jobs

were decentralized in 1960. The negative path coefficient implies that when jobs were highly decentralized in 1960 relatively few suitable sites were available for new jobs. The moderate effect of ANNEX60, on the other hand, probably reflects the availability of suitable sites near the city center and perhaps some attraction of jobs to population concentrations. (A small level of this variable reflects a high degree of dwelling unit suburbanization.)

In regard to the role of the other exogenous variables, we found that densely settled central cities failed to attract whites, or lost them to their suburbs, largely because they lacked the space to accommodate new housing, a conclusion implied by the large joint effect with ANNEX60 which accounted for 97% of the joint effect of DENSITY60 on CCTOSUB shown in Table 3, and 80% of the joint effect of DENSITY60 on INTOSUB. The strong correlation of JOBSUB60 with ANNEX60 also accounts for most of the "effect" of JOBSUB60 and region on the two measures of white suburbanization. Thus, the ability of a central city to annex surrounding territory over the decades before 1960 emerges as a key factor in its subsequent ability during the sixties to control suburbanization. The factor also accounts for much of the correlation of density, region, and job suburbanization with population suburbanization.

DISCUSSION

The results have a number of implications for public policy as well as ecological and popular explanations of white suburbanization. Considering the theoretical implications, the general conclusion is that the structural characteristics of metropolitan areas are the dominant constraints on white decisions to move to the suburbs. The role of "push" factors is less important even though they are a small part of the process linking structural variables to white suburbanization. The most general summary statement is that whites are drawn to the suburbs rather than pushed to them.

The strong effects of density are not for the reasons given in media interpretations;

whites apparently do not avoid densely settled central cities, or move from them, because of any desire for the "wide open spaces" of the suburbs, or to avoid any attendant "hustle and bustle." Such an inference would require an independent or direct effect, which is not observed. Instead white movement to the suburbs of dense cities simply reflects the lack of space for new housing. This strongly supports Schnore's (1965) assertion that whites began moving to the suburbs during the late forties because the space to accommodate the massive post-war demand for new single family dwelling units was generally not available in the central cities.

It is also consistent with the findings of Duncan et al. (1962) and Guest (1973) for census tracts that population redistribution is largely a function of the redistribution of dwelling units. This is, in retrospect, hardly surprising. In fact, it is surprising only in the context of the widespread emphasis given to the presumed roles of civil disorder, crime and racial consideration—factors which also have no apparent impact on the location of new housing.

Nonetheless, it is substantively interesting that despite the considerable variation in the degree of different kinds of civil disorder among central cities, including riot seriousness and riot frequency, only the latter appears to affect white suburbanization, and the effect is quite small. The rate of white suburbanization is essentially the same in metropolitan areas where the central cities experienced crippling strikes by municipal employees, large scale civil rights protests, lengthy school closings, and severe riots, as in those areas where the central cities were quiescent along all of these dimensions.

A partial explanation of the small impact of riots may be that, regardless of their severity, or even their frequency, the overwhelming majority of whites are not directly affected. The race riots of the sixties were confined almost entirely to black residential areas. Attacks on whites were focused on the policemen and firemen who attempted to control them, and the fires and looting rarely spread to white

neighborhoods. In the case of civil rights protests, while whites may or may not favor them, it appears that they did not sufficiently disrupt daily routines to lead whites to avoid or to leave central cities.

However, strikes by municipal employees, especially teachers and perhaps transit workers, clearly affect the life style of central city residents. The lack of correlation between strikes and white suburbanization may simply mean they were not sufficiently prolonged, or did not affect sufficiently large numbers of people, to have been a major consideration in residential decisions. It does not follow that there is no level of these variables that would affect white residential behavior, only that levels observed in the sixties did not have any visible impact.

The lack of any direct effect of the relative size of the black population also contradicts popular explanations. However, in retrospect, this may be easily explained. There is considerable evidence that the residential areas of blacks and whites were almost completely distinct; for all practical purposes whites were as segregated from blacks in 1970 as in 1960 and Sørensen approached the maximum possible (Sørensen et al., 1974). Moreover, percent black is positively related to degree of residential segregation: blacks in cities with relatively large black populations are more segregated residentially than are those in cities with small black populations (e.g., Jobu and Marshall, 1971). Thus, whites need not be concerned about the size of the black population.

Differences in the impact of crime rates on in-migrants compared with central city residents probably reflects the greater awareness of the latter. Unlike riots or even strikes and other manifestations of civil disorder, relatively little publicity is given to crimes in a given city by the media in other cities. Consequently, in-migrants to a metropolitan area are probably not aware of the degree of threat they may experience if they settle in the central city. This is manifestly not the case for current residents. Crimes are reported by local media and, if widespread, residents are likely to know, or know of, victims, as well as having been victimized themselves.

Finally, the analysis has numerous implications for urban policy-makers. It particularly suggests that attracting new housing to central cities can significantly affect current trends. Probably the most effective policy is government subsidy for acquisition of large parcels of land suitable for residential use—in short, a vigorous extension of current urban renewal projects.

Of course, such a strategy is politically feasible and morally defensible only if the groups, largely the poor and minorities, dependent upon housing destroyed by this process, can be relocated in the suburbs. This, in turn, points to the necessity for evolving strategies to overcome the effective resistance of suburbs to such relocation—resistance which has historically centered on zoning ordinances and refusal of realtors to show homes to otherwise qualified blacks in white areas (e.g., Downs, 1973).

CORRELATES OF DELINQUENCY: THE ILLUSION OF DISCREPANCY BETWEEN SELF-REPORT AND OFFICIAL MEASURES*

American Sociological Review 1979, Vol. 44 (December):995-1014

This paper reviews the research literature concerning the extent to which studies of delinquency that use official records produce results compatible with studies of delinquency that use self-reports of adolescents. Particular attention is given to sex, race, and social class as correlates of delinquency. The notion that official and self-report methods produce discrepant results with respect to sex, race, and class is largely illusory. In reaching conclusions of discrepancy several techniques have been used in the literature; the most general is the assumption that self-reports and official data tap the same domain of behavior. When the domain limitations of self-reports are recognized (and other illusory techniques are abandoned), the conclusion of general consistency between self-reports and official correlates for sex, race, and class emerges. This consistency and other evidence from victimization surveys, studies of the reliability and validity of self-reports, and studies of biases in criminal justice processing, suggest that both official data and self-reports provide valid indicators of the demographic characteristics of offenders, *within the domain of behavior effectively tapped by each method.*

For 160 years scholars have attempted to solve the crime measurement problem by cataloging sources of possible error in existing techniques, by deriving the facts about crime from theories of criminality, and by simply accepting observed results at face value. About twenty years ago, a new dimension was added to this enterprise. Following preliminary and unsystematic work by Porterfield (1946) and Wallerstein and Wyle (1947), Short and Nye (1957) introduced the self-report method of measuring delinquent behavior. This new method produced results apparently contrary to those produced by established methods. Consequently, it did

not settle the measurement issue. On the contrary, scholars could then catalog sources of error in either of two techniques; they could derive either of two sets of facts from criminological theory; and they could accept either of two sets of facts at face value. In short, the basic results of criminological research remained open to dispute. No simple conclusion about demographic correlates or causes of crime could command acceptance by more than a portion of interested scholars. And so it remains today.

Whatever approach one takes to a criminological issue, its vulnerability to the measurement question quickly surfaces. A recent example is the apparently definitive paper by Tittle, Villemez, and Smith (1978). Drawing on 35 studies and 363 separate estimates of the class/crime relation, Tittle et al. conclude that the assumed negative correlation between social class and criminality is a "myth." They also conclude that the discrepancy between self-report and official results in years prior to 1964 probably reflects class-linked biases in official processing. Given the history of the field, we may safely assume that both of these conclusions will provide little more than a starting point for

* Address all communications to: Michael J. Hindelang; School of Criminal Justice; State University of New York; Albany, NY 12222.

This project was supported by Grant No. MH27778-03 awarded by the Center for Studies of Crime and Delinquency, National Institute of Mental Health, U.S. Department of Health, Education, and Welfare. In connection with this project, published self-report data and ten self-report data sets have been analyzed for the past several years, the results of which are in Hirschi, Hindelang, and Weis (forthcoming). An earlier version of this paper, "The Great SES/Delinquency Debate: Much Ado About Nothing," was read at the 1977 annual meeting of the American Society of Criminology.

future debate.¹ As long as there is disagreement on the methodological and statistical underpinnings of such conclusions, assessments of the empirical evidence, however thorough, will continue to produce ambiguous results.

In this paper we argue that the invention of self-report procedures could have resolved the crime measurement problem by showing consistency in results across methods. We argue further that it did not resolve the crime measurement problem because of continued misinterpretation of self-report findings. Such misinterpretation may be traced to a variety of techniques, all of which create the illusion² of discrepancy between the correlates of official and self-reported delinquency when, in general, no such discrepancy has been demonstrated. These arguments will be illustrated by using sex, race, and social class as examples.

ORIGINS OF THE SELF-REPORT METHOD

In historical context, the self-report method may be seen as a device for studying delinquency in "nondelinquent" populations, where all "official"³ measures of delinquency (e.g., police records, court records, and incarceration) were too stringent to reveal adequate variation. Given this purpose, those constructing self-report instruments could not reasonably include offenses like homicide and rape for which observed variance in a small general population sample would have to be treated as error rather than true variance.⁴ In fact, the requirement that

items produce meaningful variation further skewed self-report instruments toward behavior occurring frequently in "nondelinquent" samples. Although perfectly reasonable from a statistical perspective, such items are almost by definition outside the domain of behavior that elicits official attention.

Early attempts to produce cumulative, unidimensional (Guttman) scales eliminated the very infrequent (and generally more serious) offenses from this already skewed pool. The final Short/Nye (1957) scale items are:

Driven a car without a driver's license or permit.
 Skipped school without a legitimate excuse.
 Defied parents' authority (to their face).
 Taken little things (worth less than \$2) that did not belong to you.
 Bought or drank beer, wine or liquor (including drinking at home).
 Purposely destroyed public or private property that did not belong to you.
 Had sex relations with a person of the opposite sex.

Although they scaled by Guttman criteria, four additional items had to be eliminated by Short and Nye because they were committed too infrequently by their noninstitutional respondents:

Run away from home.
 Taken things of medium value (between \$2 and \$50).
 Taken things of large value (over \$50).
 Used or sold narcotic drugs.

In rankings of offense seriousness by samples of the general population, the seven Short/Nye items retained are virtually off the scale; in one study they do no better than 125th in a list of 140 items (Rossi et al., 1974).⁵ Such offenses, which constitute the core of self-report items widely used into the early 1970s (Hindelang, 1971; Hirschi, 1969), are largely outside the domain even of police contacts (e.g., Wolfgang et al., 1972: Table 5.3). In recent research, there has been a move-

¹ In May, 1979, Elliott and Ageton (1979:25) reported that results from their national self-report survey show that "lower class youth are found disproportionately among high frequency offenders." Elliott and Ageton cite Tittle et al. (1978).

² We do not use the word illusion as synonymous in any way with deception. Rather, we use it to refer to the appearance of inconsistency where it need not or does not exist.

³ Most of the data in this paper using official measures of delinquency are data on arrests or contacts drawn from police files. Occasionally, data relating to court records or incarceration are also referred to as "official" delinquency data.

⁴ For example, Porterfield's (1946:41) results showing one murder in his sample of 200 college men strain credibility. Subsequent self-report researchers have excluded the homicide item and have uncovered no murderers in their samples.

⁵ Breaking a plate glass window in a shop ranked 125th, theft of a book from a store ranked 129th, and repeated truancy ranked 136th. As described in the Rossi et al. (1974) study, these offenses are more serious than the typical offense implicitly described in parallel self-report items.

ment toward the inclusion of more serious items, but even current instruments as a whole are dominated by nonserious delinquent offenses (Elliott and Ageton, 1979; Farrington, 1973; Gold and Reimer, 1975; Berger and Simon, 1974).

Even apparently serious items in current self-report instruments turn out on inspection to allow the respondent to report behavior that would be hard to construe as serious delinquency. Gold (1970:25), for example, used a probe technique to screen out nonchargeable offenses. The remaining chargeable offenses were then scored for frequency (F) and seriousness (S). One respondent, *among the 10% most delinquent in Gold's sample*, had scores of $F = 12$ and $S = 10$. Gold (1970:30) summarizes this youth's delinquent activities.

... [at age 12] he and a friend had knocked down a tent in a neighbor boy's back yard—the aftermath of an earlier mud-throwing fight.

That winter, he had shoplifted gum a few times from a neighborhood store.

On turning 13, he had begun to lie regularly about his age to cashiers at movie theaters.

In June, 1961, he had shoplifted a cartridge belt from a hardware store and later given it to a friend.

The month after, he had taken an address book from a department store.

In the summer of 1961, he and a friend had helped themselves to several beers from his friend's refrigerator.

In late August, 1961, he and another friend had twice raided an orchard not far from R's home, taking ripe pears and unripe apples and grapes. They ate the first, and threw the rest at various targets.

In September, 1961, he had lifted a hunting knife from a sporting-goods store just for something to do. "We took it back the next day, snuck it back in."

He regularly carried a hunting knife under his jacket "for protection" when he went collecting Friday nights on his paper route.

All subsequent discussion of self-report results should be interpreted with Gold's serious delinquent in mind: "more serious" refers to the upper part of a very limited seriousness range. When the reader encounters a statement such as "class is uncorrelated with delinquency," it is safe to assume that as delinquency has

been measured by self-reports, the level does not generally exceed that illustrated by Gold's case history of one of his most delinquent boys. Regardless of how often it is said that self-reports measure primarily trivial offenses (e.g., Gold, 1966), it is easy to forget that they do. Self-report offenses are routinely treated as equivalent to official offenses in comparing correlates of delinquency (e.g., Tittle et al., 1978; Elliott and Voss, 1974). When the results using the two criteria are inconsistent, it seems to follow that one or both measurement procedures is faulty. An alternative interpretation remains: it may be simply inappropriate to compare the correlates of trivial and serious offenses. In fact, the most general technique for creating the illusion of discrepancy between self-reports and official statistics is to imply or state that both tap the same domain of "chargeable" offenses.⁶

The domain of delinquent offenses has two critical components relevant to comparison of methods. The first relates to behavioral content or type of offense. In Uniform Crime Report (UCR) arrest data, the most commonly used distinction is between violent and property offenses (a distinction that produces important differences in demographic correlates); in self-reports, distinctions often relate to offense types such as theft, property damage, drugs, school offenses, and violence. The second relates to seriousness, both within (e.g., amount of theft) and across (e.g., school versus violent) offense types. Seriousness is often judged on the basis of harm to the victim or potential adverse consequences to the offender (e.g., in the penal code). These methods of assessing seriousness generally produce highly consistent results across population subgroups (Sellin and Wolfgang, 1964; Rossi et al., 1974). The consequence of a failure to take such domain considerations into account is an undifferentiated comparison of self-report and official results.

⁶ Actually, self-report results are often argued by self-report researchers to measure delinquent behavior, while official data are said to measure the actions of officials. This suggests that despite their obvious domain limitations, self-report results are superior to official results, because they alone tap the appropriate domain.

Table 1. Sex Ratios for Commonly Used Self-Report Items, Ranked by Magnitude of Mean Sex Ratio

	Range	Mean	Median	Number of Samples ^a
Runaway	.35-1.43	.96	1.00	13
Drink	.85-1.75	1.28	1.28	20
Truancy	1.06-1.91	1.34	1.28	12
Theft LT \$2	1.16-2.05	1.63	1.75	12
Drive without license	1.08-3.32	1.73	1.50	8
Sex relations	1.51-83.86 ^b	2.76	2.86	7
Theft \$2-\$50	1.48-5.03	2.79	2.70	12
Damage/destroy property	1.71-5.15	3.13	2.92	14
Take car	1.48-13.26 ^c	3.27	3.37	15 ^c
Gang fight	.92-4.60	3.61	3.28	11
Beat up/assault	1.17-6.50	3.64	3.61	10
Theft GT \$50	1.43-6.60	3.86	3.68	11
Strong arm	1.00-8.00	4.54	2.87	10

^a The samples on which this table is based are reported in: Akers (1964); Columbano (1974); Elliott and Voss (1974); Hirschi (1969); Kratcoski and Kratcoski (1975); Short and Nye (1958); Walberg et al. (1974); Gold and Reimer (1975); Gold (1970); Hindelang (1971); Wechsler and Thum (1973); Slocum and Stone (1963). Where the published data were reported by age group, race, or geographic region we have computed more than one ratio.

^b The mean value excludes an extreme outlier of 83.36 (Porterfield, 1946).

^c The mean value excludes an extreme outlier of 13.26 (Walberg et al., 1974).

The trivial items in self-report scales swamp more serious items when, as is common, global simple sum scales are used. To the extent that the correlates of serious items differ from the correlates of trivial items, global scales will reflect the correlates of trivial delinquency. Similarly, to the extent that the correlates of certain *types* of delinquency differ, global scales will mask these differences.

CONTENT, SCORING, AND CORRELATES OF SELF-REPORTS

Sex

When one decomposes self-report instruments and examines the correlations of individual items with external variables, one is immediately struck by the variation in the results. Sex differences in self-report data are highly contingent on item content. If we take into account the content and the limited seriousness tapped by self-report items, the pattern of this variation resembles patterns in official data. Variation in these differences is illustrated in Table 1 where commonly used self-report items are shown. Significantly, the lowest mean sex ratio in the table is for running away (.96); this ratio in UCR arrest data on juveniles has hovered around 1.0 for the years covered by these

data.⁷ Another possible comparison is for "beat up/assault." As Table 1 shows, the mean sex ratio in self-report studies is 3.6, which is similar to that for "other assault" in the UCR (e.g., 1968=5.0; 1972=3.5). Significantly, precise comparisons of standard self-report items with other UCR offenses are not possible. However, those items even crudely comparable to UCR categories produce roughly comparable results. For example, the sex ratio for the self-report offenses of theft of items worth more than \$2 is about 3.3 and that for larceny-theft in UCR data on juveniles has fallen from 4.7 in 1964 to 2.5 in 1976. When a violence component is added to the theft (strong-arm), the self-report mean sex ratio is 4.5, whereas the sex ratio for robbery in UCR data has not been lower than 12 in recent years. Self-report "strong-arm" offenses are not equivalent to UCR robbery offenses; however, given the progression in the size of the mean sex ratios shown in Table 1 as the items move from theft of less than \$2, to theft of \$2-\$50, to theft of more than \$50, to strong-arm, it seems reasonable to suppose that if self-report items picked up

⁷ Where possible from published self-report literature, we have used prevalence ratios; some of our ratios are, however, based on incidence data. UCR data reflect the incidence of arrest.

Table 2. Sex Ratios in Indexes of Self-Reported Delinquency

	Ratio	Study
Any delinquency (Index F)	1.64	Gold (1970)
"High" delinquency (Index F)	11.40	
Any seriousness (Index S)	2.38	
"Very high" seriousness (Index S)	12.00	Elliott and Voss (1974)
Any delinquency (%)	1.03	
Nonserious offenses (\bar{X}), Jr. High	1.48	
Nonserious offenses (\bar{X}), Sr. High	1.58	
Serious offenses (\bar{X}), Jr. High	2.66	
Serious offenses (\bar{X}), Sr. High	2.89	
Scale scores, 8 Nye/Short items (\bar{X})	2.11	Akers (1964)
Any theft (%)	1.94	Dentler and Moore (1961)
High theft (%)	2.26	
"Significant" delinquency (\bar{X}) 1967	1.97	Gold and Reimer (1975)
1972	1.47	
Seriousness scale (\bar{X}) 1967	2.77	Hindelang (1973)
1972	2.82	
1 or more recent acts (%)	1.72	
3 or more recent acts (%)	3.88	
5 or more recent acts (%)	6.00	

serious robberies the sex ratio would move toward that in the UCR.⁸

Sex ratios on the order of 2:1 (or less) are frequently found for global self-reported delinquency scales (see Table 2). These are often compared with official data that show a ratio on the order of 4 or 5 to 1. Since the magnitude of the sex ratio depends upon the frequency and seriousness cutting points used in self-report research, and since officials also take such considerations into account in deciding whether to process offenders—both frequency (prior record) and seriousness are factors affecting official decision (Wolfgang et al., 1972: chap. 13)—it is misleading to compare self-report and official results ignoring such considerations (see Reiss, 1975).

The content, seriousness, and fre-

quency considerations that help to account for apparent discrepancies between self-report and official results with respect to sex need also be examined for race, the correlate that consistently produces the largest discrepancy between self-report and official results.

Race

An abundance of studies use official data to compare blacks and whites (e.g., Eaton and Polk, 1961; Wolfgang et al., 1972; Kelley, 1977). All show marked racial differences, with blacks substantially overrepresented among offenders. While self-report research has not often attended to race—in part, because self-report samples tend either to be drawn from small town white populations or to be nationally representative, in which case there are too few blacks for meaningful comparisons—existing data raise serious questions about the compatibility of official and self-report results. In fact, until very recently the range of sex-specific black to white ratios found in self-report samples did not overlap with the range of ratios found in official data. In general, self-report studies simply have not found substantial racial differences (Chambliss and Nagasawa, 1969; Epps, 1967; Gold, 1966; Gould,

⁸ We should note here that as seriousness increases, the proportion of general adolescent respondents reporting involvement generally diverges from .5; hence the variance of more serious items is typically smaller than that for less serious items. The result is that ratios tend to increase somewhat with skewness, even though *absolute* percentage differences in self-report involvement (e.g., between sexes) may be similar for less serious and more serious items. However, in these data, the odds ratios for less serious and more serious items are different, indicating differential effects by seriousness level. Such differences are reflected in our simple ratios.

1969; Hirschi, 1969; Lively et al., 1962; Williams and Gold, 1972; Gold and Reimer, 1975).

The hypothesis that blacks are no more likely to engage in illegal behavior than whites but are discriminated against by the police may be plausible, but the small or nonexistent racial biases shown in studies of differential selection (e.g., Wolfgang et al., 1972: Table 13.5) simply cannot account for the large racial differences in offending suggested by official data (e.g., Wolfgang et al., 1972: Table 5.3). Furthermore, an independent third source of data, reports of victims on the race of offenders in victimization surveys, produces results that parallel official data for common-law personal crimes (Hindelang, 1978).

How, then, can we account for the "inconsistency" of self-reports with official and victimization data? We hypothesize that this discrepancy, like the apparent sex discrepancy, is attributable to the great weight self-report instruments give to minor offenses. Consistent with this hypothesis, although Hirschi (1969) reports no significant relation between total self-reported delinquency and race, examination of the race differences in three individual theft items shows progressively greater black involvement as the seriousness increases. For theft of items worth less than \$2, theft of items worth \$2-\$50, and theft of items worth more than \$50, the black to white prevalence ratios are .9, 1.24, and 1.75, respectively. However, because the percentages of all respondents reporting involvement in the acts are 51, 21, and 9, respectively, the simple sum scale is dominated by the least serious item, when only the two more serious items, in which blacks report more involvement, are likely to come to the attention of the police.⁹ Compatible findings are reported by Williams and Gold (1972) and Elliott and Voss (1974), where slightly larger racial differences are found in offenses they classify as serious.

Data clearly indicating that self-report

items approaching the seriousness of offenses in police records (particularly violent offenses) reveal racial differences are provided by Berger and Simon's (1974) study of more than 3,100 adolescents in Illinois. Using factor analysis, they created homogeneous subscales before making racial comparisons; fortunately, this procedure had the consequence of separating the more serious items from the rest of the set. Their normal deviance factor, containing such items as "cheating on exams," "skipping school," and "drinking," showed a very high proportion of all respondents reporting involvement, with a general tendency for whites to report slightly greater involvement than blacks. The theft scale, made up of standard self-report items such as "property damage," "theft of little things," and "keeping or using stolen goods" revealed no racial differences. In contrast, their violence scale, which includes items such as "used a weapon," "been in a gang fight," and "strong-armed robbery," produced consistent black/white differences. Among males, the ratio of black to white percentages is about 2:1; and among females the ratios tend to be higher (nearly 3:1) than the male ratios, a finding consistent with official data (Berger and Simon, 1974:151).

If the general argument that blacks and whites differ in *serious* delinquent behavior but are more similar in less serious forms of delinquent behavior is correct, then this phenomenon should be reflected, at least to some extent, in official data as well. Table 3 presents data from UCR arrests for 1976. This table shows the ratio of black arrest rates to white arrest rates for selected UCR crimes.

Consistent with the argument outlined above, the ratio of black to white arrest rates is much larger for the more serious index offenses (3.49:1) than for the less serious nonindex offenses (1.71:1). Noteworthy is the finding that among index offenses the ratio for violent crimes is substantially larger than that for property crimes (9.08:1 vs. 3.14:1). Not only are the former more serious, but they also have a clearance rate two and one-half times greater than the latter.* Thus, assuming these arrest data by race are pro-

⁹ See Gottfredson and Hindelang (1976) regarding the association between the victim's likelihood of reporting an event to the police and the value of stolen property.

Table 3. Ratio of Black to White Arrest Rates of Persons under 18 Years of Age, for Selected Offenses, United States, 1976^a

Index Offenses	3.49
Violent	9.08
Property	3.14
Nonindex offenses	1.71
Aggravated assault	5.69
Other assault	4.47
Forcible rape	9.64
Other sex offenses (excludes forcible rape and prostitution)	3.22
Vandalism	1.23
Driving under the influence	.29
Drunkenness	.56
Runaways	.94

^a The ratios in this table were derived by taking the black to white raw arrest ratios and adjusting them by the black to white ratio for the general population (1:8).

Source: Kelley (1977: Table 35).

portional to offending behavior by race, black youths are probabilistically more likely than white youths to be arrested, simply because violent crimes have higher clearance rates than do property crimes.

Other arrest data shown in Table 3 provide support for our hypothesis that the general failure of self-report studies to parallel official data on race may be attributable to the more trivial nature of self-report than official items. Comparing the ratios for aggravated and "other" assaults it can be seen that, relative to whites, blacks are slightly more often arrested for the former (more serious) offense than the latter (5.69 vs. 4.47); similarly, comparing black to white arrest rate ratios for rape and "other" sex offenses, blacks are arrested relatively more often for the more serious rape offenses than for "other" sex offenses (9.64 vs. 3.22).

In Table 3, it is also possible to examine items commonly found in self-report instruments—vandalism, drunkenness, driving under the influence, and running away. For these petty offenses, the black/white ratios are much smaller (or in most cases reversed, 1.23, .29, .56, and .94, respectively) than those for violent or property index offenses. The overall pattern of findings in Table 3 is therefore compatible with the hypothesis that the general failure of self-report studies to find the overrepresentation of blacks relative

to whites in official data is attributable in large part to an overabundance in current self-report instruments of items tapping less serious, more numerous offenses.

Data available from the national victimization survey being conducted by the Bureau of the Census for the Law Enforcement Assistance Administration also shed light on the relationship between the seriousness of the offense and the race of the offender. In these surveys, about 130,000 persons are interviewed twice a year regarding the personal crimes of rape, robbery, assault, and larceny from the person. Although these offenses are generally much more serious than those elicited by self-report instruments, there is a wide range of seriousness in the incidents reported to survey interviewers.¹⁰

The data in Table 4 from the national survey for 1976 include only victimizations in which the offender was reported by the victim to have been under 18 years of age. Victimization have been scored for seriousness using the Sellin-Wolfgang (1964) method, and weighted to be representative of the United States as a whole. Attending first to the total row in Table 4, it can be seen that black offenders account for almost half of the personal victimizations reported to survey interviewers. When it is recalled that blacks in the United States account for less than 15% of the juvenile population, it is clear that, for these offenses, black youths are substantially overrepresented among offenders in relation to their representation in the general population. Despite the heterogeneity of these events with respect to seriousness, they are on the whole considerably more serious than the events typically elicited by self-report instruments (most meet the Uniform Crime Report criteria for Part I offenses). For the

¹⁰ For example, it has been found that about half of the incidents reported involved neither injury nor financial loss to the victim—i.e., they were attempts (Hindelang, et al., 1978: chap. 2). Nonetheless, even these *relatively* minor events fall within UCR definitions. Similar to the problem faced by self-report instruments, each offense category contains a variety of offenses that are heterogeneous with respect to seriousness. Thus, a strict test of our hypothesis would require that self-report instruments specify rather carefully the behavior included even within a serious offense category (e.g., robbery).

Table 4. Perceived Race of Offender in National Crime Survey Victimization, in which Offenders were Perceived to be under 18 Years of Age, by Seriousness Level, United States, 1976^a

Seriousness ^b	Perceived Race of Offender					
	White		Black		Total	
1	(588,126)	50%	(589,480)	50%	(1,177,606)	100%
2	(626,849)	53%	(546,245)	47%	(1,173,094)	100%
3	(457,178)	53%	(410,203)	47%	(867,381)	100%
4	(89,263)	33%	(178,667)	67%	(267,930)	100%
Total	(1,761,415)	51%	(1,724,594)	49%	(3,486,009)	100%

^a Includes only offenders perceived to be under 18 years of age. Each incident is weighted according to the number of offenders involved. Excludes offenders of "other" races, groups of offenders of mixed races, and incidents in which offender characteristics were unknown to the victim.

^b Sellin-Wolfgang seriousness weights were recoded as follows: 0-1 = 1; 2-3 = 2; 4-5 = 3; 6 or more = 4. See Sellin and Wolfgang (1964: Appendix F) for scoring details.

less serious victimizations, blacks account for about the same percentage of all offenders as do whites. More important, however, for the most serious victimizations—those most likely to be reported to the police (Gottfredson and Hindelang, 1979)—blacks account for two-thirds of the offenders. Once again, these data are congruent with the hypothesis that self-reports fail to find racial differences in large part because self-report instruments generally do not pick up the most serious kinds of street crime. The compatibility of victimization survey results and UCR arrest data (Hindelang, 1978) severely damages the hypothesis that arrest data merely reflect racial biases inherent in police practices.

Up to this point, we have shown that various sources of data on delinquency are consistent when attention is given to obvious differences in content. As noted, it would be unreasonable to expect greater correspondence for sex and race than that actually observed, owing to domain limitations of self-report instruments used to date. With this background, we turn to social class, where an abundance of "illusions of discrepancy" may be found.

Social Class

Unlike sex and race, social class data are not available for either UCR arrestees or for offenders in victimization surveys. Thus, if understanding the relationship of social class to serious offending is our aim, data limitations are much more severe for social class than for sex or race.

Until publication of "The Myth of Social Class and Criminality" (Tittle et al.,

1978) the dominant view in the field was that summarized by Gordon (1976:201): "One of the most thoroughly documented known crime and delinquency relationships is that with socioeconomic status."¹¹ Tittle et al. (1978) take strong exception to this position for data from recent years. They note that self-reports have always shown a near-zero relationship with social class while studies using official statistics have shown moderate to strong inverse associations with class in the pre-1964 period. This leads them to the conclusion that there must have been class-linked biases in criminal justice processing in the earlier period. This suggestion (and data supporting it) is not new. Indeed, it was suggested by the first study to compare the SES-delinquency relationship for self-report and official criteria (Short and Nye, 1957).

Short and Nye compared the social class distributions of high school and training school boys. The resultant 2 × 4 table (training school vs. high school by four social class categories) produced a contingency coefficient of .45. Among the high school boys, the contingency coefficient between social class and *self-reported* delinquency (a dichotomized global scale) was .10, a nonsignificant relation ($p = .3$). This shift in the contin-

¹¹ In support of this statement Gordon lists 23 studies published in the three previous decades, including many of the better-known works in the field. Close inspection reveals that only four of these are American studies that allow estimation of individual-level relations; only two of these permit direct comparisons between self-reports and official data with respect to the SES-delinquency relationship.

gency coefficient from .45 to .10, when the criterion became self-reported rather than official delinquency (i.e., institutionalization), had significant implications for criminological research and theory.

On the level of *theory*, these results provided fuel to the then nascent labelling and conflict approaches to delinquency. They did much to quicken interest in *research* on official processing of offenders. More important for present purposes, they established the expectation that *valid* self-report procedures will often produce results contrary to official data. Ironically, the Short/Nye data do not support this expectation when the contingency coefficient (or any other marginally dependent measure of association) is used appropriately as the criterion. On the contrary, the self-report and official results show remarkable consistency with respect to estimates of the class-delinquency association in the general adolescent population.

This fact was overlooked because of two factors that contributed to the illusion of discrepancy between official and self-report results. The first, discussed in another context by Tittle et al. (1978), was the implicit comparison of the Short/Nye self-report results with previously established ecological-level¹² class delinquency relations, which often ran as high as $-.7$ or $-.8$, depending on the indicator of class (e.g., Shaw and McKay, 1942). A greater ecological than individual level association is expected even when precisely the same delinquency measure is used, simply as a function of the aggregation of individual level data. Hence, a similar discrepancy when *different* criterion measures are used need say nothing about the compatibility of the measures. Second, the contingency coefficient used by Short and Nye substantially overestimated the magnitude of the relation between SES and delinquency by using the official criterion (institutionalization). Because C is marginally dependent, it is misleading to compare an association based on the general high school population with an association based on an unweighted aggregation of institutionalized and general

population adolescents. In the table that produced a contingency coefficient of .45, the institutionalized boys ($N = 146$) constituted almost 15% of the total. This table (Short and Nye, 1957: Table 1) misleadingly suggests that 39% of all lower class boys, and even 5% of the highest class, were in a training school.

A reasonable estimate of the prevalence of institutionalization in training schools by age 18 is approximately 1% for white males (Gordon, 1976: Table 2). At any given time the proportion of the general adolescent population in training schools is much less than 1%. For illustrative purposes, we recalculated the contingency coefficient in the Short/Nye data allowing the training school population to be 1% of the total sample. Under these conditions, the coefficient drops from .45 to .11, which leaves class no better able to predict official than self-reported delinquency ($C = .10$) by this criterion.¹³

Two additional studies are often cited as evidence of discrepancy in the association of social class with self-reports as compared to official data. Williams and Gold (1972) present data collected by Gold in 1967. In their paper they utilize a major device for creating the illusion of discrepancy: despite the fact that the official and self-report data are consistent, they treat them as discrepant. Williams and Gold make an apparently important distinction between "delinquent behavior" (as measured in self-reports) and "official delinquency." In justifying such a distinction they focus on the SES-delinquency relation.

The often cited finding of official delinquency as a lower-class phenomenon is a product of the above mentioned filtering process. This finding, *which is by our defini-*

¹² See Nye et al. (1958) for a list of empirical studies dominated by ecological research.

¹³ For those concerned with the modifiability of measures of association as a result of manipulating the marginals, it is important to note that our secondary analysis of the raw data from this study revealed that the relation between class and *self-reported* official delinquency (measured by "Have you ever been arrested and convicted . . . ?") in the Short/Nye data ($C = .06$) is even smaller than our .11 estimate of the relation between official delinquency and class. To the extent that researchers accept self-reports of delinquent behavior as reliable and valid, it follows that self-reports of official records are at least as reliable and valid.

tion quite valid, now takes on new meaning: official identification of and response to delinquent behavior shows a strong relationship to lower-status juveniles. However, it does not necessarily mean that lower status youths are involved in more delinquent behavior than any other social status group. (Williams and Gold 1972:210, emphasis added)

The premise of Williams and Gold's (1972:e.g., 210, 211, 217) article states that official and self-report data produce different results. Throughout their discussion, they use class to illustrate differences between the correlates of official delinquency and delinquent behavior. Nevertheless, they actually report, virtually without comment, a gamma of $-.02$ (1972:225) for occupational prestige and frequency of police records, and, for the same white male group, gammas of $.05$ (frequency) and $.12$ (seriousness) for occupational prestige and self-reported delinquency. Neither the frequency of self-reported delinquency nor the frequency of police records was significantly correlated with social status among white males.¹⁴ Contrary to the thrust of Williams and Gold's discussion and the title of their paper, the SES-delinquency correlations for males in the 1967 National Survey of Youth do not depend on the method of measurement.

The presentation format used by Elliott and Voss (1974: Table 4-7) illustrates yet another analytic technique that has fed the illusion of discrepancy: a failure to disaggregate data properly in order to examine potentially confounded effects. Elliott and Voss present data on police contacts per 100 self-reported delinquent behaviors that show marked differences by class status. For example, in the highest of five SES classes there were 1.692 police contacts per hundred self-reported offenses compared to 7.382 in the lowest category, a finding apparently strongly supportive of the discrepancy position. That is, in the absence of differential self-report measurement error by class and differential selection by the police, these ratios would

be expected to be identical across classes. However, these data are problematic because the Elliott/Voss table (1974: Table 4-7) is not disaggregated by either sex or ethnicity (closely associated with delinquency and/or social class).¹⁵ Reanalysis of the Elliott and Voss raw data shows, in fact, that ethnicity and sex were confounding the relationship between social class and these ratios.¹⁶ One-way analysis of variance of the ratios by social class within homogeneous sex-ethnicity groups reveals no significant effect of social class on these police-selection ratios. Again, the illusion of discrepancy turns out to be just that.

The recent systematic and thorough review by Tittle et al. (1978) concludes, in part, that a discrepancy between self-report and official results is evident. Unfortunately, their analysis suffers from shortcomings that compromise its conclusions. Not only do the authors accept self-report results at face value and assume that their domain is comparable to that in official data, which we have argued here is inappropriate, but they also use an analytic technique which can produce the illusion of discrepancy when none necessarily exists. In their secondary analysis of the published literature, Tittle et al. use regression analysis to account for variation in the magnitude of the class/crime association (gammas) as a function of such variables as the nature of the crime criterion (self-report vs. official), year of data collection, and sample size. Rather than making direct comparisons of self-report and official results, when both were available in a single study, Tittle et al. rely upon statistical adjustment to control for the effects of other variables:

Given instances using two samples of exactly the same type and size, drawn from

¹⁴ The values shown for the Gold subjects in our Table 5, discussed below, differ from these coefficients primarily because the latter are based on a trichotomy for class and grouped data on the F scale.

¹⁵ A small number of adolescents with extreme scores on the numerator and/or the denominator of these ratios may have disproportionately affected the mean ratios presented by Elliott and Voss (1974).

¹⁶ Unfortunately, the original investigators provided us with data regarding official delinquency records only for part of the period covered by their study. These data include about 50% of the official delinquencies recorded for the full period of the original study.

precisely the same areas in a given year and employing the same number of defined social classes, the equation shows that we may expect the study employing official statistics to produce a gamma showing a .10 greater negative association for the same relationship than an instance employing self-report data (Tittle et al., 1978:649).

This conclusion suggests much more precise control of the dimensions in the regression equation than is in fact possible. Most self-report studies have been conducted in the period (post-1970) when official studies had virtually ceased (Tittle et al., 1978: Table 3). Nonetheless, some direct comparisons are possible. All American studies allowing such comparisons are shown in Table 5.

The oldest data in Table 5, collected in 1957 by Reiss and Rhodes (1961), show identical asymmetric Somers's d 's ($-.16$) using the self-report or the official criterion to assess the class/delinquency association.¹⁷ In contrast, the Tittle et al. comparison for this period (1950-59)—based on three studies using a self-report criterion and seven using an official criterion—showed very divergent mean gammas of $-.04$ and $-.43$ for the self-report and official criteria, respectively. (In terms of gammas, the Reiss and Rhodes coefficients for self-report and official data are $-.36$ and $-.33$, again virtually identical).

Most of the data in our Table 5 are from the period (1960-69) in which the Tittle et al. comparisons show the mean official gamma to be $-.22$ and the mean self-report gamma to be $-.11$. Our direct comparison of results shows that the two criteria produce very similar associations. In this period, the mean official Somers's d is $-.02$ (mean gamma = $-.11$) and the mean self-report Somers's d is $.01$ (mean gamma = $.00$).¹⁸ In both the Tittle et al.

indirect comparisons and in our own direct comparisons, the differences in the size of the class-crime association using the official and the self-report criterion are slight for the 1960-69 period; in the 1950-59 period, however, the large discrepancy reported by Tittle et al. is not replicated using direct comparisons. Owing particularly to official/self-report differences in the domains tapped, these comparisons must be viewed as extremely crude. In light of this and the general consistency shown in Table 5, conclusions of discrepancy between the two measures are at best weak.

Our earlier admonition that omnibus scale comparisons can be misleading should not be ignored. Unfortunately, however, the fact is that with respect to social class, adequate data for making offense-specific comparisons among the social classes are simply unavailable. There is no published source of police data that is large enough to permit class comparisons of the kind shown for race in Table 3; there is no source of self-report data that permits reliable interclass comparisons for categories of serious crime. For example, Williams and Gold's (1972) data represented in the Tittle et al. table and in our Table 5 have both official and self-report data from the mid to late 1960s. However, in this sample of 847 respondents, only 4% or 34 males and females had police records. In the Elliott and Voss sample of 2,617 respondents, although 26% had records of offenses more serious than traffic infractions, nearly nine out of ten of these were for petty theft, running away, vandalism, truancy, and liquor offenses. In light of the variations by offense in the magnitude of sex and race relationships in both sources of data, omnibus comparisons are far too crude to permit confident conclusions that discrepancy exists.

¹⁷ In $r \times 2$ tables where the independent variable is the dichotomy neither gamma nor Somers's asymmetric d is marginally dependent. In 3×3 and larger tables both gamma and asymmetric Somers's d are marginally dependent (Somers, 1962:808). Gamma has the disadvantage of being biased upwards by small cell counts which often result from severe skewness. Somers's d is less sensitive to small counts in some cells.

¹⁸ Interestingly enough, in the 1960-69 period the gammas from our direct comparisons in studies

where both self-report and official data are available are smaller than those reported by Tittle et al., which illustrates once again that the magnitude of the association between class and delinquency is sufficiently variable from one sample to another that a conclusion of discrepancy cannot be predicated on an assumed value, even if this value has been estimated from a regression model based on a large number of data points.

Table 5. Percent with Police Record of Delinquency and Percent with Self-Reported Delinquency,^a across Social Class (Secondary Analyses of Raw Data)

Study	Date of data collection	Sample subgroup	Social class indicators	Social class groups			Gamma	Asymmetric Somers's d
				Blue Collar	White Collar	High		
Reiss and Rhodes	1957	White males (n = 7963)	Father's occupation	6 (4,661)	3 (3,302)		-.33	-.16

^a Self-reported delinquency cut-off points were selected to be as close as possible to the 75th percentile on the delinquency distribution. Measures of association shown are based on the full tables (usually 3x4).

^b Reiss and Rhodes (1962: Table 1), excluding truancy and traffic offenses.

^c Derived from Reiss and Rhodes (1962: 732).

In sum, although illusions of discrepancy abound, we are hard-pressed to locate persuasive evidence that self-report and official methods produce discrepant results. Our conclusion is consistent with studies of the psychometric properties of self-report measures of delinquency. In terms of reliability, many studies indicate that test/retest or split-half measures of the reliability of self-reports are on the order of .9 (Kulik, Stein, and Sarbin, 1968; Dentler and Monroe, 1961; Elmhorn, 1965). Although validity is inherently more difficult to establish, a variety of approaches to this question have produced generally consistent results. Studies using the nominated or known group method (Nye, 1958; Erickson and Empey, 1963), concurrent checks of official records (Hardt and Peterson-Hardt, 1977; Elliott and Voss, 1974; Farrington, 1973; Erickson, 1972; Kulik, Stein and Sarbin, 1968) and reports of informants (Gold, 1970), have found self-reports to have considerable validity.¹⁹ Thus, in terms of the standard criteria of reliability and validity, self-report measures of delinquency are not obviously defective *within the domain of content they tap*.

If the domain limitations of self-reports may be safely ignored, if the results for a sample of individuals may be compared with results from areal units or with improperly weighted aggregates, if standard disaggregation procedures may be ignored in analysis, and if assertions contrary to data presented are accepted, then, and only then, it seems to us, is the conclusion of discrepancy between self-report and official results warranted. Since these procedures are not acceptable, we believe the conclusion of discrepancy is not justified by currently available evidence.

In short, we believe the evidence on the crime measurement issue is now sufficient to allow resolution of many of the apparent inconsistencies among various measures of criminality. This evidence suggests to us that: (1) official measures of

criminality provide valid indications of the demographic distribution of criminal behavior; (2) self-report instruments typically tap a domain of behavior virtually outside the domain of official data; (3) within the domain they tap, self-report measures provide reliable and valid indicators of offending behavior; (4) the self-report *method* is capable of dealing with behavior within the domain of official data; and (5) in practice, self-report samples have been inadequate for confident conclusions concerning the correlates of offending behavior comparable in seriousness to that represented in official data.

IMPLICATIONS

The reaction to essentially illusory "inconsistencies" between the correlates of self-report and police data has taken one of two general forms: either self-report methodology has been rejected, or sex, class, race, and other biases have been imputed to criminal justice system representatives. The first of these reactions is inconsistent with evidence of the basic reliability and validity of the self-reported method. But as long as discrepancy is accepted, the conclusion that self-reports are reasonably reliable and valid will merely shift attention to official data as the probable source of discrepancy. Of course, the hypothesis that the procedures producing official data are biased against the less powerful segments of society antedates self-report research (e.g., Bonger, 1916). It seems fair to say, however, that the major impetus behind empirical studies of the differential selection of delinquents by officials has been the lack of a substantial relationship between social class and race on the one hand and self-report measures of delinquency on the other. Interestingly enough, studies of the administration of juvenile justice have failed to locate sufficient bias against powerless groups in official processing to account for their higher rates of criminality. Once the seriousness of the instant offense and prior record of the offender are taken into account, apparent class bias plays only a relatively minor role in the generation of official data (Wolfgang et

¹⁹ The polygraph study of Clark and Tift (1966) is often cited as evidence of validity. We are in essential agreement with De Fleur (1967) that because of its design, this study provides evidence only about reliability.

al., 1972, Table 13.5; Cohen, 1975; Terry, 1967; Hohenstein, 1969). Our earlier analyses suggested that no class bias should have been expected, since direct comparisons reveal little or no self-report/official discrepancy, and the bias uncovered by processing studies is not sufficiently strong to account for differences found in official data for race and sex.²⁰

Consistent with these findings, comparisons of UCR arrest data with victimization data for race and sex (Hindelang, 1978; 1979) have shown remarkable consistency. As noted above, because official data are inadequate for making reliable estimates of the substantive class-official data relation, it is premature to conclude that there is no relationship, except for those minor offenses measured reliably in typical (i.e., Short/Nye type) self-report scales. For offenses that are likely to result in deprivation of liberty (i.e., UCR index level offenses) the class-crime relationship simply has not been examined adequately. If class-linked criminal justice system biases are relatively small for serious common-law offending, the heavy overrepresentation of poor and uneducated persons in jails and prisons (e.g., LEAA, 1977:20), probably reflects a class-serious offending association for UCR index crimes. Our previous discussion suggests that, in principle, properly constructed self-report instruments should be capable of confirming this association if it is actually present. However, the research problem is more complex than this solution suggests.

Let us assume that the most serious offenders, say those involved in UCR index offenses, are in fact disproportionately poor and uneducated as the prison population data suggest. Would a properly constituted self-report instrument (or even an

examination of police records for the general population) be expected to substantiate this class difference in illegal behavior? If the research design were similar to that typically employed in self-report surveys, there is good reason to believe that the results would be problematic. In the Wolfgang, Figlio, and Sellin (1972: Table G1.1) cohort data, the prevalence (from age 7 through age 17) of contact with the police for at least one index offense was 8.62% for white males and 20.43% for nonwhite males. Weighted to the racial distribution for the United States, the prevalence of contact with the police (through age 17) for an index offense is about 10% for (urban) males. If we assume that one out of two index offenders does not have any police contacts for index offenses during adolescence, the prevalence of at least one index offense would be about 20%.²¹ However, since this 20% figure is for all of adolescence and the typical self-report survey has a one-year reference period, an ideal self-report survey would have to be sensitive to class differences around an annual population prevalence rate of 2 or 3%. Thus, if the lower class index offense prevalence rate were double that of the middle class rate, the study would have to be sensitive to rate differences of two or three percentage points.

Given such skewness in the distribution of a dependent variable, what kind of self-report study is required to find appreciable class differences? First, the sample selected must generate enough self-reported delinquency for reliable measurement of serious crime. This can be done in one of two ways: either the sample size must be extremely large or the sample must be stratified by variables known to be correlated with serious delinquent behavior. If the extremely large sample route is taken, perhaps the best analogue to sample size requirements is the sample

²⁰ The Piliavin and Briar (1964) study is often cited as showing racial biases operating through demeanor. However, what is almost always ignored is the fact that in this study of sixty-six youth, neither the seriousness of the offense nor the prior record of the juvenile was controlled because N's were too small for reliable estimates. Piliavin and Briar (1964:209-12) state, however, that for serious personal crimes and for offenders with prior records, demeanor was much less significant.

²¹ It is important to note that 37% of those coming into contact with the police for index offenses were not arrested (Wolfgang et al., 1972: Table 13.1). Hence more than one-third of the index contacts recorded by the police were judged (by their release of the juvenile) to be insufficiently serious to warrant arrest.

size required to measure reliably criminal victimizations suffered by Americans. (As noted above, the Census Bureau conducts interviews with more than 130,000 persons twice per year.) The largest nationwide self-reported delinquency study published to date is Gold's National Survey of Youth, which conducted interviews with 1,395 11 to 18 year old males and females, 182 of whom were black. In estimating the distribution of delinquency by social class for 13 to 16 year old males, Gold had 115 or fewer males in each of his three social class cells. If delinquency of the UCR index-type is of interest, these numbers are inadequate for reliably distinguishing class effects. Even in studies that include examination of police records for general population samples, the proportion of *police*-recorded offenses of UCR index seriousness is so small that the task of finding reliable class differences would require much larger sample sizes than those typically used.

An alternative to such extremely large samples is to sample probabilistically within strata known to differ sharply on self-reported delinquency—for example, subjects with and without court records of serious delinquency. To the extent that the stratification variable is related to serious self-reported delinquency, the absolute sample size required to measure the dependent variable reliably will be reduced. By knowing the proportion of respondents falling into each stratum, in the population as a whole, the data can be weighted to produce unbiased estimates of population parameters.²²

Second, regardless of sampling method, if the population estimate of the class-crime association is summarized by a measure of association that is affected by the marginal distribution of the dependent variable, the tremendous skew of index-level offending in the general population would reduce to near zero even very large differences across classes in *rates* of of-

fending. Third, when we add the problem of nonresponse, it seems unlikely that serious offenders will be as cooperative as nonoffenders. For example, there is strong evidence that those known to have police records are less likely to participate in such surveys than those without police records (e.g., Hirschi, 1969: Table 5).

Thus, for all of these reasons, the substantive limits of conclusions regarding the consistency of self-report and official delinquency measures with respect to class are clear. At present, data on the most serious portion of the distribution of delinquent *behavior* are insufficient to allow class comparisons and hence confident substantive conclusions. However, if we move to the point of incarceration where social class data on serious offenders are available, we find the substantial class differences assumed by traditional sociological theories. At the other (non-serious) extreme, there do not appear to be class differences in adolescent behavior for the relatively minor offenses that make up the great bulk of what is collected in self-report studies and recorded in local police files.²³

The "trivial content" objection to the self-report method has had little impact on the revision of self-report instruments or sampling procedures. Although self-report instruments have gradually come to include somewhat more serious items, they are still dominated by less serious items. As shown above, even within the restricted seriousness range available in extant self-report studies, there is plentiful evidence that seriousness and item content affect self-report results. With respect to sex, these dimensions appear to account for much of the apparent discrepancy between official and self-report findings. Similarly, with respect to race, both self-report and victimization data suggest an overinvolvement of blacks in more serious offenses; some self-report (e.g., Berger and Simon, 1974) and virtually all official data suggest strong race

²² Parenthetically, it is important to note that this design will improve sampling efficiency and will be appropriate even if there are biases involved in labelling persons as court delinquents. As long as court records are related to delinquent behavior, stratifying on court records will improve sampling efficiency.

²³ Even at the court level, most researchers are surprised at the triviality of the offenses described in official accounts of juvenile misconduct. Such descriptions are consistent with Gordon's prevalence estimates reported above (see also note 21).

effects for violent offenses. Thus, explicit attention to seriousness and content differences across methods must precede comparisons of their results. In the absence of sharply increased sample sizes or more efficient designs, however, the inclusion of more serious items in self-report instruments will not solve the problem of reliably measuring index offenses with the self-report technique.²⁴

In historical perspective, it can be seen that students of crime have focused their attention on at least three measures of youthful misconduct: the Uniform Crime Reports index offenses, local police and court data, and self-report offenses. Because these data are all taken to be measures of delinquent behavior, it is easy to assume that they should produce similar findings without further adjustment for obvious differences among them. Close examination reveals that this assumption is unfounded. These measures are rarely available on the same subjects and the overlap in their content is often minimal. Wholesale comparisons of results using these three measures are therefore inappropriate and, in themselves, say little or nothing about the extent of criminal justice system biases or the adequacy of the self-report method.

RESEARCH NOTE

EFFECTS OF SOCIOECONOMIC FACTORS ON THE RESIDENTIAL SEGREGATION OF BLACKS AND SPANISH AMERICANS IN U.S. URBANIZED AREAS*

DOUGLAS S. MASSEY

Princeton University

American Sociological Review 1979, Vol. 44 (December):1015-1022

INTRODUCTION

According to theorists of human ecology, differences in the degree of residential segregation between groups is a result of differences in socioeconomic variables such as income, education, and occupation (Burgess, 1923; Park, 1926). With respect to racial segregation, this hypothesis has been effectively discredited by a number of studies (Taeuber and Taeuber, 1964; 1965; Taeuber, 1968; Farley, 1977; 1979). At the same time, the hypothesis has received some support from studies of ethnic segregation. Several researchers have reported significant correlations between ethnic segregation and various indicators of socioeconomic status (Duncan and Lieberman, 1959; Lieberman, 1961; 1963; Darroch and Marston, 1971; Guest and Weed, 1976). However, there is some inconsistency in the evidence. While Korbin and Goldscheider (1978) report that ethnic concentration generally decreases with social class, Darroch and Marston (1971) and Kantrowitz (1973) found no such relationship.

The Spanish-American population represents an interesting group on which to further examine the social class basis of segregation. Like the black population, it represents a large, highly visible urban

minority with a history of discrimination and socioeconomic exploitation. Similar patterns of residential segregation might therefore be expected. This paper compares patterns of black and Hispanic segregation with respect to the effects of socioeconomic variables. Following the tenets of human ecology, and in light of previous findings regarding ethnic segregation, we hypothesize an inverse relationship between socioeconomic class and degree of Hispanic segregation from whites.

This is not the first study to examine effects of socioeconomic factors on Hispanic segregation. Using 1960 census data, Grebler et al. (1970) presented evidence to suggest an aggregate-level correlation between economic factors and Spanish-Anglo segregation across 35 southwestern cities. However, Kantrowitz (1973) found that among Puerto Ricans in the New York metropolitan area, segregation was unaffected by social class. Aside from these two apparently contradictory studies, there has been no systematic attempt to study the impact of socioeconomic variables on Hispanic segregation, and such a study has never been undertaken on a national sample of cities using 1970 census data.

DATA

This paper presents research undertaken as part of a larger study of Spanish-American segregation in the 29 largest urbanized areas in the United

States. Urbanized areas were chosen for analysis instead of SMSAs because the concern here was with urban segregation. In 1970, about 22% of the population outside of urbanized areas, but within SMSAs was classified as rural (U.S. Bureau of the Census, 1972: Table 47).

All data have been taken from the Fourth Count Summary Tapes, File A, of the 1970 Census of Population, which present cross-tabulations of white, black, and Spanish-American populations by education, income, and occupation within census tracts of SMSAs (U.S. Bureau of the Census, 1970). Since tracts can at times straddle boundaries of urbanized areas, a tract was included in an urbanized area only if the majority of its population lived inside the boundary.¹

For its detailed cross-tabulations, the Census Bureau defines Spanish Americans differently in different regions of the country. In New York, New Jersey, and Pennsylvania, Spanish Americans are defined on the basis of Puerto Rican birth or parentage. In the Southwest (Arizona, California, Colorado, New Mexico, and Texas), the population consists of persons of Spanish language, plus persons of Spanish surname but not of Spanish language. In the remaining states, the Spanish-American population is defined simply as persons of Spanish language.

In general, differences between populations defined on the basis of Spanish language and Spanish language plus surname are relatively minor. Inclusion of persons of Spanish surname but not of Spanish language in the Spanish-American population of the Southwest has the effect of lowering slightly the level of measured segregation, compared to populations defined on the basis of Spanish language alone. Moreover, there are no apparent differences in patterns of segregation across socioeconomic status categories.

On the other hand, the Puerto Rican population of the Northeast is very different from other Spanish populations, primarily in that Puerto Ricans are iden-

tified explicitly on the basis of birth or parentage. Persons of third or greater generation are thus not included in this population. Perhaps as a result, Puerto Ricans are much more segregated than other Spanish groups, and exhibit very different patterns of segregation across social classes. Therefore, Puerto Ricans will generally be treated separately from other Spanish populations in this paper.

METHODS

The effect of social class on Hispanic segregation will be assessed in two ways. First, indices of dissimilarity will be computed within socioeconomic status categories defined on the basis of variables such as education, family income, and occupation. Such indices measure the degree of segregation between ethnic or racial groups of the same socioeconomic class. These within-class indices may vary from a minimum of zero (no segregation) to a maximum of 100 (total segregation), and represent the proportion of minority that would have to change tracts to achieve evenness *within* socioeconomic categories (Duncan and Duncan, 1955b; Taeuber and Taeuber, 1965). The strengths and weaknesses of the index of dissimilarity as a measure of segregation are well known (cf. Duncan and Duncan, 1955a; Cortese et al., 1976; Taeuber and Taeuber, 1976; Winship, 1977; Massey, 1978), and although there remains some debate on the pros and cons of the measure, it is employed here in the absence of any suitable alternative and any clear evidence of its inappropriateness. However, because the index can be inflated by random factors when small numbers are involved (as in some socioeconomic status categories), within-class indices will be interpreted as indicating relative levels of segregation across social classes. At the same time, care will be taken to avoid small within-class frequencies that could lead to possible biases.

The effect of socioeconomic factors on segregation will also be assessed by examining the relationship, across urbanized areas, between Hispanic segregation and various indicators of socioeconomic status. A negative relationship

¹ The laborious task of locating tracts within or outside of urbanized areas had already been done for the 29 urbanized areas by Farley (1977), who generously made the information available for this study.

SOCIOECONOMIC FACTORS AND RESIDENTIAL SEGREGATION 1017

between Spanish socioeconomic status and extent of residential segregation from whites is expected.

RESULTS

1. Segregation within Socioeconomic Classes

Because the size of Spanish-American populations is relatively small in many of the 29 urbanized areas under study, cross-classification by socioeconomic status produces within-class frequencies that are often very small, particularly among the upper strata. Therefore, analysis of patterns of within-class segregation is restricted to ten of the 29 urbanized areas with large Spanish populations.² New York is not included among these ten because its Spanish-American population consists entirely of first- and second-generation Puerto Ricans, and will be considered separately.

For each of the ten urbanized areas, indices of dissimilarity were calculated within social classes defined on the basis of education, family income, and occupation. The resulting segregation scores were then averaged within classes and plotted in Figures 1, 2, and 3 to depict patterns of Spanish-white, Spanish-black, and black-white segregation across socioeconomic classes.³ In Figure 3, occupational groups are ordered on the x-axis from low to high socioeconomic status using Duncan's (1961) SEI scores.

These figures clearly support the hypothesis of a negative relationship between socioeconomic status and degree of Spanish-white segregation. Whether measured in terms of education, income, or occupation, Spanish-white segregation declines unambiguously with increasing socioeconomic class.

² The ten urbanized areas are Chicago, Dallas, Denver, Houston, Los Angeles, Miami, San Diego, San Francisco, San Jose, and Washington, D.C.

³ For all segregation scores computed in this paper, white and black populations were defined net of Spanish Americans. To do this, black Spanish and white Spanish were identified by socioeconomic category within each census tract and subtracted from the corresponding total black and white populations reported for that tract on the Fourth Count Tapes.

Figure 1. Average Segregation by Level of Education, 10 Urbanized Areas

As one would expect from the literature on racial segregation, Spanish-black and black-white segregation both remain very high across all socioeconomic classes. While Spanish-white segregation declines 33 points from the lowest to highest edu-

Figure 2. Average Segregation by Level of Family Income, 10 Urbanized Areas

Figure 3. Average Segregation by Occupational Group, 10 Urbanized Areas

cational category, there is no apparent change in the degree of either black-white or Spanish-black segregation. Note, however, that the level of Spanish-black segregation is generally somewhat less than that of black-white segregation. Similar results are observed when social classes are defined on the basis of income.

The decline in Spanish-white segregation is also apparent across occupational groups, even though it is much more erratic. This uneven pattern is not surprising given the rather broad, heterogeneous occupational groupings employed by the Census Bureau. However, the correlation between occupational status and average Spanish-white segregation is -0.78 , and there is a decline of 23 points between the lowest and highest occupational status groups. Considering the crudeness of the occupational groupings, the data reveal a fairly clear tendency for Spanish-white segregation to decrease as one moves from blue-collar to white-collar occupational categories. As with other measures of social status, there is no apparent decline in either Spanish-black or black-white segregation across occupational groups.

The above results provide strong evidence of a potent socioeconomic effect

Figure 4. Segregation by Level of Education in the New York Urbanized Area, Compared to Segregation in Miami and a Set of 10 Urbanized Areas

operating on Spanish-white segregation among the ten cities under consideration. However, when the effect of social class is examined for persons of Puerto Rican birth or parentage in New York, a very different picture emerges, as can be seen from Figure 4, which presents patterns of segregation by education in New York.

Note first of all that, unlike Spanish populations in other urbanized areas, there is no evidence of any decline in Puerto Rican-white segregation with increasing social class. Second, the overall level of Puerto Rican-white segregation is considerably higher than that of Puerto Rican-black segregation. These patterns are similarly repeated when income and occupation are used as indicators of social class.

The reason for this discrepancy with previous results is not at all clear. In particular, we cannot say whether these findings reflect the uniqueness of New York as a metropolitan area, or Puerto Ricans as a Hispanic population. While explaining this mystery is beyond the scope of this paper, we can eliminate one seemingly plausible hypothesis.

One might theorize that the absence of a

discernible socioeconomic effect among Puerto Ricans could relate to the fact that, unlike other Hispanic groups considered here, Puerto Ricans are defined on the basis of their "foreign" birth or parentage, thus excluding all higher generation individuals. If one assumes that socioeconomic status increases with generations spent in the United States, and that segregation declines within increasing generation, then the lack of a decline in segregation among Puerto Ricans could be due to the systematic absence of less-segregated native stock Spanish within the higher socioeconomic classes.

This hypothesis was tested by comparing patterns of within-class segregation in New York and Miami. Miami's Spanish population is itself 86% foreign stock, primarily of Cuban birth or parentage. If it is the absence of native stock Spanish that accounts for the lack of a socioeconomic effect among New York Puerto Ricans, then we would expect Miami to show little or no decline in Spanish-white segregation with increasing social status.

As can be seen in Figure 4, this is not the case. Although the decline is not as regular as the ten-city average, Miami, nonetheless, displays a clear decrease in the level of Spanish-white segregation across educational categories, a finding repeated using income and occupational data.

Thus anomalous results found with respect to New York Puerto Ricans cannot easily be explained as artifacts of their definition in terms of Hispanic birth or parentage rather than Spanish language.

2. Socioeconomic Factors and Interurban Variation in Segregation

We have thus demonstrated a clear pattern of decline in the level of Spanish-white segregation with increasing socioeconomic status. It seems logical, therefore, to hypothesize that the higher the overall social status of a city's Spanish population, the lower should be the level of Spanish-white segregation. In other words, there should be an inverse relationship between the overall socioeconomic status of an urbanized area's Spanish population and the degree of its segregation from whites. At the same time, we expect no relationship between overall social status and the level of either Spanish-black or black-white segregation.

Table 1 presents least-squares estimates of relationships between segregation and indicators of socioeconomic status across the 29 urbanized areas. Again, the hypothesis of an inverse relationship between Spanish-white segregation and socioeconomic status is amply confirmed. Interurban variation in socioeconomic indicators such as median education, me-

Note: For relationships involving Spanish-white and Spanish-black segregation, measures of socioeconomic status pertain to the Spanish population, while for those relationships involving black-white segregation, the measures pertain to the black population.

dian income, and percentage in high status occupations⁴ accounts for between 65 and 80% of the variation in Spanish-white segregation scores. At the same time, there is little evidence of any relationship between socioeconomic variables and either Spanish-black or black-white segregation. The only coefficient to achieve significance was that relating black occupational status to the level of black-white segregation. However, occupational status obviously explains much less of black-white than Spanish-white segregation. In short, interurban relationships between socioeconomic status and segregation reinforce and strengthen previous results pertaining to patterns of segregation within social classes.

SUMMARY AND DISCUSSION

The above results reveal a marked dissimilarity between patterns of black and Hispanic segregation. As other scholars have previously noted, the high degree of segregation between blacks and whites cannot be accounted for by socioeconomic factors alone. In contrast, patterns of Spanish-white segregation are very highly related to social class. Results indicate that as socioeconomic status increases, within-class segregation between Spanish Americans and whites falls off steeply. Moreover, variation in the degree of Spanish-white segregation between cities is highly related to variation in the general socioeconomic level of cities' Spanish populations. A notable exception to the pattern of strong social class effects was the Puerto Rican population of New York, which exhibited remarkably high levels of segregation from whites across all social classes.

Interestingly, Spanish Americans were found to be quite highly segregated from blacks at all socioeconomic levels. While the overall degree of Spanish-black segregation was somewhat less than the very

high level of black-white segregation, their patterns across social class strata were almost parallel, suggesting that Spanish Americans resemble other whites very closely with regard to their residential behavior towards blacks.

In general, these findings confirm the ecological hypothesis that spatial relations between groups can be understood in terms of social and economic variables, and support theorists such as Burgess (1923) and Park (1926), and the later findings of the Duncans (1955b), the Taeubers (1964), and Lieberman (1963). Some scholars have recently criticized the ecological perspective for placing too much emphasis on the reduction of ethnic segregation through socioeconomic processes, pointing instead to the remarkable persistence of ethnic segregation in American cities (Darroch and Marston, 1971; Kantrowitz, 1973). Our findings are also consistent with this point of view, for in spite of the very obvious socioeconomic effects, Hispanic segregation is never eliminated by controlling for social class. Even among the highest strata, Spanish-white segregation persists at some level. We thus concur with Guest and Weed (1976), who similarly found merit in the views of ecological theorists as well as their critics.

The findings of this paper also suggest a subtle departure from usual derivations from ecological theory. Theorists usually have hypothesized ethnic segregation to be a function of social status differences between groups (cf. Darroch and Marston, 1971; Guest and Weed, 1976). Our results suggest that differences may not be the important variable in operation. If social class differences were crucial determinants of segregation, then, when we control for such differences, the results should yield reduced levels of segregation within all status categories. In fact, within-class segregation scores are reduced only as one approaches the upper socioeconomic strata. In spite of their equal socioeconomic statuses, Spanish Americans and whites within the lowest strata are quite highly segregated. Given this fact, one might conclude that it is absolute, and not relative, socioeconomic status that is important in determining levels of ethnic segregation. As larger

⁴ To obtain the percentage in high status occupations, the 11 occupational categories were ordered in terms of Duncan's (1961) SEI scores and divided at the median to form two groups: high status and low status occupations. The high status group had a mean status rating of 51.4, compared to a value of 12.8 for the low status group.

shares of an ethnic population enter (over time) the higher status categories, ethnic segregation should be correspondingly reduced—irrespective of status relative to other groups.

This conclusion is consistent with processes of ethnic assimilation suggested by the recent work of Korbin and Goldscheider (1978). According to their findings, higher status categories are less segregated because of their higher residential mobility. Individuals in the upper socioeconomic strata are progressively more likely to move out of areas of ethnic concentration than those in lower strata, with the ultimate result being a decline in segregation with increasing status. Since spatial concentration and residential stability are crucial to the maintenance of patterns of ethnic socialization and interaction, ethnic identification is progressively weakened among the upper socioeconomic strata, and assimilation occurs. If such is the process underlying residential desegregation, then *relative* socioeconomic status is not the key variable, although it may play some role. Rather it is the *absolute* advance of ethnic groups up the socioeconomic scale that affects underlying processes of residential mobility, which in turn give rise to reduced levels of residential segregation.

Such a process is consistent with the results presented here. Moreover, it explains the remarkable persistence of ethnic segregation noted by Kantrowitz (1973) and others. Even if an ethnic population such as Spanish Americans were to achieve a socioeconomic distribution equal to that of native white Americans, segregation would not be eliminated, since a large share of the Spanish population would remain in the less mobile, more segregated lower strata.

In conclusion, the implications of the above results with respect to future trends in residential segregation and assimilation of Spanish Americans are clear. Socioeconomic advancement should lead to significantly reduced levels of residential segregation among Spanish Americans, and ultimately to greater assimilation. According to the relationships depicted in Table 1, if Spanish Americans among the 29 urbanized areas were to achieve a me-

dian education level of 12 years, expected Spanish-white segregation would fall to around 35, compared to its current value of 44. Thus, over time, the potential for residential desegregation and assimilation among Spanish populations is considerable, particularly in comparison with blacks, who are highly segregated from other ethnic and racial groups of all social classes.

search concerns work on basic sociological concepts and their measurement.

■ **ROBERT J. ANTONIO** (The Contradiction of Domination and Production in Bureaucracy) is Associate Professor in the Department of Sociology at the University of Kansas. He is doing research on the long-term roots of modern state bureaucratic society. His work focuses on the role of the historical development of reason/rationalization in the larger system's social, economic, political, and ideological development.

■ **DAVID JACOBS** is Assistant Professor in the Department of Sociology at the University of Maryland Baltimore County. His most recent publication (with David Britt in the August, 1979, *Social Problems*) involved a test of conflict theory using the number of killings by policemen. He is currently working on a theoretical treatment of mobility systems within organizations and an empirical reconciliation of political and dual labor market explanations for economic stratification.

■ **DOUGLAS LEE ECKBERG** (The Paradigm Concept and Sociology) is Assistant Professor in the Department of Sociology at the University of Tulsa. In October, 1979, his book, *Intelligence and Race: The Origins and Dimensions of the IQ Controversy*, was published (Praeger). In press (*Annual Review of Sociology*) (and co-authored with Joe R. Feagin) is "Discrimination: Motivation, Action, Effects, and Content." He is doing research on the development of beliefs (within the realm of science) concerning women's intelligence. **LESTER HILL, JR.** is Associate Professor at Jacksonville (Alabama) State University. Currently, he is researching the relationship between belief systems and behavior, and factors affecting changes in belief systems.

■ **JOHN M. STAHURA** (Suburban Status Evolution/Persistence) is Assistant Professor in the Department of Sociology and Anthropology at Purdue University. His current areas of interest are suburban crime-rate models and projections, and the modelling of growth and decline of central cities.

■ **ROBERTA G. SIMMONS** (Entry into Early Adolescence) is Professor in the Department of Sociology at the University of Minnesota. Two longitudinal researches presently occupy her. One, a study of Milwaukee school children, looks at the determinants of self-esteem in different school environments in early and late adolescence. The second, a study of kidney-transplant recipients (and of the family members who did and did not donate kidneys to them), examines family stress, family decision-making, and changing self-esteem in these circumstances. She has recently had two books published. In 1977, *Gift of Life: The Social and Psychological Impact of Organ Transplantation* (written with Susan D. Klein and Richard L. Simmons) (Wiley Interscience). In 1979, she was the Editor of *Research in Community and Mental Health, Volume 1* (JAI Press). **DALE A. BLYTH** is a Fellow at the Boys Town, Nebraska, Center for the Study of Youth Development. He is directing a School and Adolescent Development Research Program, exam-

ining social and psychological consequences of different school structures upon early adolescents, and is exploring the interactions of school contexts and physical development as related to self-image and social development variables. **DIANE MITSCH BUSH** is Assistant Professor in the Department of Sociology at the University of Arizona. A chapter, "Socialization Processes through the Life Course" (written with Roberta G. Simmons), for *Sociological Perspectives in Social Psychology* (Basic Books) is forthcoming. Her research currently is on repression of the labor movement in the southwest during the World War I era. **EDWARD F. VAN CLEAVE** is a Ph.D. candidate in the Department of Sociology at the University of Minnesota, where his research is currently involved with a two-sample investigation of the impact of family structure upon early adolescent self-esteem. His work also involves construction of a formal theory for the development of interpersonal commitment.

■ **KENNETH I. SPENNER** (Temporal Changes in Work Content) is a post-doctoral Fellow at the Center for the Study of Youth Development at Boys Town, Nebraska. His research interests include occupational characteristics and classification systems. He is collaborating with Luther Otto and Vaughn Call in a longitudinal study of career entry.

■ **HARVEY MARSHALL** is Associate Professor in the Department of Sociology at Purdue University. In his current research he is analyzing black and white suburbanization, by socioeconomic status; as well as return migration to central cities by socioeconomic status.

■ **MICHAEL J. HINDELANG** is Professor in the School of Criminal Justice, SUNY, at Albany. His research includes projects on the methodology of self-reported delinquency, the use of victimization data to study serious youthful offending, and the utilization of criminal justice statistics. In 1978, his *Victims of Personal Crime: An Empirical Formulation for a Theory of Personal Victimization* (written with Michael J. Gottfredson and James Garofalo) was published (Ballinger). Forthcoming is his most recent book, *The Measurement of Delinquency by the Self-Report Method* (with Travis Hirschi and Joseph G. Weis). **TRAVIS HIRSCHI**, also Professor in the SUNY, Albany, School of Criminal Justice, is working on Method Effects in Self-Report Measurement, and collaborated on the aforementioned book. **JOSEPH G. WEIS** is Assistant Professor in the Department of Sociology, University of Washington, Seattle, where he is researching the measurement of delinquency; crime projections; and the role of peer influence on delinquent behavior. He also collaborated on the here-mentioned book (with Hindelang and Hirschi).

■ **DOUGLAS S. MASSEY** is a post-doctoral Fellow in the Graduate Group in Demography at the University of California, Berkeley. His investigations of patterns of migration between Mexico and the United States focuses on both legal and illegal migration. He is also analyzing patterns of neighborhood transition and spatial segregation among Hispanic populations in United States cities.

AMERICAN SOCIOLOGICAL REVIEW

Published Bimonthly by the American Sociological Association

CONTENTS OF VOLUME 44, NUMBERS 1-6

ARTICLES

Akers, Ronald L., Marvin D. Krohn, Lonn Lanza-Kaduce, and Marcia Radosevich Social Learning and Deviant Behavior: A Specific Test of a General Theory ..	635
Allison, Paul D. See J. Scott Long	816
Andrews, Kenneth H., and Denise B. Kandel Attitude and Behavior: A Specification of the Contingent Consistency Hypothesis	298
Antonio, Robert J. The Contradiction of Domination and Production in Bureaucracy: The Contribution of Organizational Efficiency to the Decline of the Roman Empire	895
Attewell, Paul, and Dean R. Gerstein Government Policy and Local Practice	311
Ballmer-Cao, Thanh-Huyen See Volker Bornschieer	487
Bean, Frank D., and Gray Swicegood Intergenerational Occupational Mobility and Fertility: A Reassessment	608
Black, Donald Comment: Common Sense in the Sociology of Law	18
Blalock, H. M. The Presidential Address: Measurement and Conceptualization Problems: The Major Obstacle to Integrating Theory and Research	881
Blyth, Dale A. See Roberta G. Simmons	948
Bollen, Kenneth A. Political Democracy and the Timing of Development	572
Bornschieer, Volker, and Thanh-Huyen Ballmer-Cao Income Inequality: A Cross-National Study of the Relationships between MNC-Penetration, Dimensions of the Power Structure and Income Distribution	487
Burstein, Paul Equal Employment Opportunity Legislation and the Income of Women and Nonwhites	367
Bush, Diane Mitsch See Roberta G. Simmons	948
Carter, Donna K. See Stanley Lieberman	347
Clignet, Remi The Variability of Paradigms in the Production of Culture: A Comparison of the Arts and Sciences.	392
Cohen, Lawrence E., and Marcus Felson Social Change and Crime Rate Trends: A Routine Activities Approach	588
Collver, Andrew, and Moshe Semyonov Suburban Change and Persistence	480
Eckberg, Douglas Lee, and Lester Hill, Jr. The Paradigm Concept and Sociology: A Critical Review	925
Felson, Marcus See Lawrence E. Cohen	588
Fine, Gary Alan Small Groups and Culture Creation: The Idioculture of Little League Baseball Teams	733
Firebaugh, Glenn Structural Determinants of Urbanization in Asia and Latin America, 1950-1970	199
Fligstein, Neil D. See Wendy C. Wolf	235
Freedman, Deborah S. See Arland Thornton	832
Frey, William H. Central City White Flight: Racial and Nonracial Causes	425
Galle, Omer R. See Walter R. Gove	59
Gerstein, Dean R. See Paul Attewell	311
Gortmaker, Steven L. Poverty and Infant Mortality in the United States	280
Gottfredson, Michael R., and Michael J. Hindelang A Study of <i>The Behavior of Law</i>	3
Gottfredson, Michael R., and Michael J. Hindelang Response: Theory and Research in the Sociology of Law	27
Gove, Walter, and Michael Hughes Possible Causes of the Apparent Sex Differences in Physical Health: An Empirical Investigation	126
Gove, Walter, R., Michael Hughes, and Omer R. Galle Overcrowding in the Home: An Empirical Investigation of Its Possible Consequences	59
Hill, Lester, Jr. See Douglas Lee Eckberg	925

Hindelang, Michael J. See Michael R. Gottfredson	3
Hindelang, Michael J. See Michael R. Gottfredson	27
Hindelang, Michael J., Travis Hirschi, and Joseph G. Wels Correlates of Delinquency: The Illusion of Discrepancy between Self-Report and Official Measures	995
Hirschi, Travis See Michael J. Hindelang	995
Hodge, Robert W. See Andrea Tyree	410
Hofferth, Sandra L., and Kristin A. Moore Early Childbearing and Later Economic Well-Being	784
Hughes, Michael See Walter R. Gove	59
Hughes, Michael See Walter Gove	126
Ihinger-Tallman, Marilyn See Irving Tallman	216
Jacobs, David Inequality and Police Strength: Conflict Theory and Coercive Control in Metropolitan Areas	913
Kandel, Denise B. See Kenneth H. Andrews	298
Kelley, Jonathan See Robert V. Robinson	38
Krohn, Marvin D. See Ronald L. Akers	635
Lanza-Kaduce, Lonn See Ronald L. Akers	635
Laumann, Edward O., and Peter V. Marsden The Analysis of Oppositional Structures in Political Elites: Identifying Collective Actors	713
